Verduyn, S. Cora, Christian Ramakers, Gabriel Snoep, Jet D. M. Leunissen, Hein J. J. Wellens, and Marc A. Vos. Time course of structural adaptations in chronic AV block dogs: evidence for differential ventricular remodeling. Am. J. Physiol. Heart Circ. Physiol. 280:H2882–H2890, 2001.—To determine the nature and time course of biventricular hypertrophy and concomitant electrical and mechanical changes after creation of complete atrioventricular (CAVB) block, six adult dogs (22–30 kg) were subjected to serial magnetic resonance imaging (MRI) and electrocardiography. After 6 days of CAVB, left ventricular (LV) mass, ejection fraction (EF), and Q-T time at a paced rhythm of 60 beats/min were already significantly increased. Maximal values were reached within 14–21 days of CAVB: LV mass, from 116 ± 11 to 143 ± 12 g; right ventricular (RV) mass, from 40 ± 3 to 55 ± 6 g; EF, from 68 ± 6% to 86 ± 5%; and Q-T time, from 285 ± 25 to 330 ± 35 ms, all P < 0.05. Cardiac output returned to baseline at day 14. End-diastolic wall thickness increased only in the RV, in which angiotensin type 1 (AT1) receptor mRNA expression was significantly greater. The autopsy correlated well with the MRI results (r = 0.98, P < 0.01). In conclusion, electrophysiological, mechanical, and structural adaptation processes after bradycardia-induced volume overload develop rapidly and are completed within 3 wk. The degree of hypertrophy was greater in the RV, which was associated with an increase in AT1 receptor mRNA.

METHODS

Propofol-anesthetized dogs were subjected to serial magnetic resonance imaging (MRI) measurements, which were preceded by determination of the electrophysiological parameters with the animals being conscious (see below).

Animal handling was in accordance with the Dutch Law on Animal Experimentation and the European Directive for the Protection of Vertebrate Animals Used for Experimental and Other Scientific Purposes (86.609/EU). The experiments were approved by the Committee for Experiments on Animals of Maastricht University and by the Committee for Infections of Academic Hospital Maastricht.

Preparation of the dogs. Six adult mongrel dogs (22–30 kg) of either sex were selected for the experiments after they had been tested in and accommodated to the laboratory environment. After two control MRI examinations in sinus rhythm (SR), CAVB was induced through a right-sided thoracotomy.

under complete general anesthesia using an injection of 37% formaldehyde at the AV junction. For details of this procedure, we refer to an earlier study (34). During this operation, an endocardial RV electrode (Vitatron, Slimtime ISP13; Dieren, The Netherlands) was inserted and exteriorized through the back of the neck to pace the dog. This specific lead was chosen after preliminary tests, which did not show interference with the MR environment. Proper care was taken before and after the experiments.

**MRI technique.** The anesthesia regimen used for the MRI experiments consisted of acepromazine (0.04 mg/kg) and was followed after 30 min by an intravenous bolus of propofol (3 mg/kg). A continuous infusion of propofol (0.3 mg·kg\(^{-1}\)·min\(^{-1}\)) was continued thereafter. No artificial ventilation had to be applied.

MR imaging was performed using a 0.5-T Gyroscan NT whole body scanner (Philips, Best, The Netherlands). With the use of a survey consisting of \(3 \times 9\) images in three orthogonal planes, the heart position was identified. Subsequently, a stack of 9-mm-thick contiguous slices, with a field view of 300 mm, was acquired, covering both ventricles in short-axis views. A cardiac-triggered gradient echo multislice-multiphase (CINE) sequence with a repetition time (TR) of 1,200 ms in CAVB dogs (equal to a paced heart rate of 50 beats/min) and a TR of \(\sim 600\) ms in SR dogs, with an echo time (TE) of 9.4 ms and a 40° flip angle, was used. Each slice was imaged in 20 phases during the cardiac cycle. The resulting images were evaluated using the MR Analytical Software System (MASS) program (version 3.0, Laboratory for Clinical and Experimental Image Processing, Department of Diagnostic Radiology, LUMC, Leiden, The Netherlands).

The lower detection limit of the MR trigger system used was 40 beats/min; therefore, an external pacemaker (5880A, Medtronic; Maastricht, The Netherlands) set at 50 beats/min was applied in all cases after CAVB. Fixed-rate pacing had the additional advantage of the same heart rate in all MRI images obtained after CAVB. On one occasion, the heart was triggered at a very high rate by the MR gradient system, needing relocation of the external connecting cable in the scanner. No other adverse effects were noted in connection with pacing in the MR environment. The duration of the MR examinations was in the order of 30–40 min, including positioning of the animal.

**Electrophysiological measurements.** Directly after the AV block procedure, the dog was paced at a cycle length (CL) corresponding to the previous SR to overcome the negative effects of anesthesia and thoracotomy. After 1 day, this paced rhythm was stopped, and the first electrophysiological measurements after CAVB were performed with the conscious dog lying quietly on the floor. Six surface electrocardiogram (ECG) leads were simultaneously registered and stored digitally using a sample frequency of 1 kHz. In this series, we chose to measure Q-T time at not only the idioventricular rhythm (IVR) but also at a paced rhythm of 1,000 ms (60 beats/min) to keep the activation fronts and QRS morphology constant.

**Time intervals.** The autopsy findings in dogs with CAVB from earlier studies in our laboratory showed a similar heart weight-to-body weight ratio after 2 wk of CAVB up to 29 wk of CAVB (Fig. 1). Therefore, the first 3 wk of CAVB were chosen as the primary time of interest, with measurements at SR (twice) and 6, 14, and 21 days after creation of CAVB. In most dogs, additional measurements were made: in three dogs at 2 and 10 days and in two dogs at 5 and 7 wk after creation of CAVB. The electrophysiological measurements were performed for up to 7 wk.

**Data acquisition and analysis.** After the MRI images were transferred to a UNIX workstation (SUN Microsystems), data were analyzed with the MASS program from base to apex. With this program, the endocardial and epicardial contours of the heart were manually traced with an optical mouse (Fig. 2). In the LV, automatic contour detection was available, which still could be corrected manually (29a). The papillary muscles were included in the endocardial contour, because they contribute to the ventricular mass. Epicardial fat was carefully excluded. The LV was measured until the appearance of the aorta, whereas the RV was determined until the start of the atria. Mass was calculated as equal to the epicardial volume minus the endocardial volume \(\times 1.05\).

An additional feature of the program allows measurement of LV wall thickness (WT) using a modified centerline method. The first (manually drawn) line was put at the posterior side of the septum, going to the left posterior wall.

The width of the RV free wall was determined at end diastole. To evaluate the accuracy of this method, a similar

![Fig. 1. Heart weight-to-body weight ratios in 31 dogs in normally conducted sinus rhythm (SR) and 84 dogs after chronic complete atrioventricular (AV) block (CAVB) of different duration. Left: body weight-corrected heart weight (HW/BW) determined at autopsy is significantly increased in the CAVB dogs \((P < 0.01)\). Right: HW/BW of the individual CAVB dogs in relation to the duration of CAVB. Dotted line, average HW/BW of the CAVB dogs. It can be seen that the individual HW/BW at 2 wk was already markedly increased and comparable with the HW/BW after longer periods of CAVB. It is for this reason that we selected the 0- to 21-day period for detailed analysis. AVB, AV block.
Most of its effects (including hypertrophy) are mediated by the ANG II type 1 (AT₁) receptor (for a review, see Ref. 13). Therefore, we assessed the AT₁ receptor mRNA expression in LV and RV tissue using a Light Cycler (Roche).

This novel technique enables semiquantitative analysis of low-abundance mRNA using real-time PCR.

Total RNA was isolated from the tissue using a CsCl₂ gradient and ultracentrifugation. Genomic DNA contamination of the samples was largely eliminated by digestion with DNase I (Promega). cDNA was synthesized using an optimized reverse transcription protocol with an oligodT-VN anchored primer (Lekanne Deprez, Academic Medical Centre Amsterdam, Amsterdam, The Netherlands, personal communication). Real-time PCR was performed with a FastStart DNA Master Sybr Green 1 kit (Roche) and dog-specific AT₁ receptor primers (17).

As an internal standard, dog-specific glyceraldehyde-3-phosphate dehydrogenase primers were used to enable correction for total RNA amounts. For all comparisons (SR LV vs. CAVB LV, SR RV vs. CAVB RV, and LV vs. RV), a separate run was performed.

**Statistics.** Pooled data are expressed as means ± SD unless otherwise indicated. Analysis of variance, followed by Student’s *t*-tests, was applied to compare the data after CAVB in respect to SR values. The AT₁ receptor differences were tested by Student’s *t*-tests. Correlation analysis was performed using Primer of Biostatistics software. Differences were considered significant if *P* ≤ 0.05.

**RESULTS**

**Validation of the MRI measurements.** The two mass measurements performed during SR were comparable and, therefore, taken together as one control; the maximum difference between measurements was 7.4 ± 5.2 g for the LV and 4.5 ± 3.7 g for the RV. These values were far below the expected increase in mass of ±20–25 g in both ventricles (34), confirming other studies (6, 20) that showed that a reliable prediction of the increase in mass was possible. The autopsy data and the MRI results showed also a good correlation (r = 0.98, *P* < 0.001).

**Development of hypertrophy in time.** CAVB caused a gradual increase in the mass of both ventricles (Table 1 and Fig. 3, top left). At 6 days (LV) and 14 days (RV), respectively, this increase in ventricular weight became significant. After 14–21 days, the progress seemed to stabilize; no further increase in mass was found, which was confirmed in the two dogs with a longer follow-up. A representative example of the long-term alteration in LV mass is shown in Fig. 4 (top) in which the extended MRI measurements were used.

With the use of MRI to calculate the increase in the ventricle-to-body weight ratio, these dogs showed an increase in the LV-to-body weight ratio from 4.5 ± 1 to 6.0 ± 0.5 kg, whereas the RV-to-body weight ratio increased from 1.5 ± 0.1 to 2.1 ± 0.1 kg (*P* < 0.05). Similar results were obtained in the much larger autopsy groups; during SR, the LV-to-body weight ratio was 4.3 ± 0.8 kg, and the RV-to-body weight ratio was 1.6 ± 0.3 kg. After CAVB, the LV-to-body weight ratio increased to 5.8 ± 1 kg, and the RV-to-body weight ratio increased to 2.6 ± 0.6 kg (*P* < 0.001 for both).

**RESULTS**

After CAVB, the LV-to-body weight ratio increased to 5.8 ± 1 kg, and the RV-to-body weight ratio increased to 2.6 ± 0.6 kg (*P* < 0.001 for both).
Nature of hypertrophy (WT and volumes). WT measurements at SR showed very comparable results, e.g., the consecutive measurements of the RV end-diastolic WT differed by 0.1 mm. With the use of the automatic detection method (Fig. 2), there was no increase in LV end-diastolic WT after CAVB (Table 1 and Fig. 3, top right). Manual measurement of LV end-diastolic WT showed the same quantitative results: 10.5 ± 1.1 mm at SR vs. 10.2 ± 1.1 mm after 3 wk of CAVB (not significant). This in contrast to the LV end-systolic WT, which increased considerably (P < 0.01; Table 1) and homogeneously; both absolutely and relatively, there was no difference in the WT increase in the different parts of the LV (Table 1).

The RV end-diastolic WT showed a significant increase from 5.8 ± 0.6 to 7.9 ± 0.9 mm at 21 days of CAVB (Table 1 and Fig. 3, top right). The assessment of the EDV showed a clear increase in LV EDV (Table 2) and RV EDV (from 58 ± 25 to 73 ± 12 ml, P < 0.05).

Comparison of RV and LV hypertrophy. The ventricles responded differently to volume overload; the relative increase in mass was much greater for the RV, most likely due to the important increase in WT (Fig. 3, top right and top left). The LV increased in mass because of a longitudinal increase in cavity size, as assessed by the number of slices covering the LV (Table 1), indicating an increase from apex to base of maximal 9 mm compared with SR. In Fig. 5, a transversal view of the heart at SR and 21 days of CAVB shows this differential structural adaptation of the ventricles.

Molecular findings. In the group of SR dogs, there was similar AT1 receptor mRNA expression in the RV and LV (Fig. 6). After CAVB, the AT1 receptor mRNA expression of the RV was significantly larger than that in the RV of SR dogs, whereas the LV did not show a change (Fig. 6).

Functional parameters. The structural adaptations were accompanied by an increase in LV EF from 68 ± 6 to 86 ± 5% at 14 days of CAVB (Table 2). In this way,
was observed from 285
With the paced rhythm (1,000 ms), an increase in Q-T
paced Q-T time and hypertrophy reached their maximum at 2 wk.
the first 2 wk, which reached a plateau at
of chronic CAVB (x-axis). There is a clear increase in Q-T time during
x-axis of all of the dogs for up to 7 wk after the creation
of 1,000 ms (y-axis) of all of the dogs for up to 7 wk after the creation
x-axis). There is a clear increase in Q-T time during
the first 2 wk, which reached a plateau at −14–21 days. Both the
paced Q-T time and hypertrophy reached their maximum at 2 wk.

the cardiac output of the CAVB dogs was maintained
after an initial reduction (Table 2 and Fig. 3, bottom right).
After 2 wk of CAVB, the LV mass-to-EDV ratio was
similar to the ratio at SR (Table 2). The RV mass-to-
EDV ratio at SR (0.77 g/ml) was also comparable with
that at 3 wk of CAVB (0.79 g/ml).
Electrophysiological measurements. Under anesthe-
psia, the Q-T interval in SR dogs (CL of 505 ± 70 ms)
amounted to 250 ± 20 ms.
The CL of IVR and the P-P interval of the conscious
dogs were stable over the week after creation of AV
block (Table 3). The Q-T at IVR increased significantly
from 260 ± 22 ms at day 1 to 285 ± 28 ms at day 21.
With the paced rhythm (1,000 ms), an increase in Q-T
was observed from 285 ± 24 to 335 ± 35 ms (P < 0.01)
(Fig. 4, bottom left). After 14–21 days, the Q-T interval
stabilized, as illustrated in Fig. 4 (bottom left and
bottom right). No changes were observed in QRS width
during pacing.

Discussion
In this study, a serial analysis of the LV and RV
adaptation processes after bradycardia-induced vol-
ume overload revealed that structural remodeling
starts very quickly and is completed within 2–3 wk
after CAVB. In parallel, i.e., in the same time frame,
electrophysiological (increase in Q-T time) and
mechanical changes (maintaining cardiac output) oc-
curred. The degree of the hypertrophy differed between
the ventricles.

Dog model of AV block. Comparing SR/acute AV
block with CAVB (>4 wk), major adaptations have
been described at the structural, functional, and elec-
trophysiological levels, which all have been confirmed
in isolated myocytes obtained from both ventricles (24,
32). In the beginning of this century, it had already
been noted that CAVB in dogs leads to biventricular
hypertrophy (7), which is not dependent on the dura-
tion of CAVB (Fig. 1) (3, 25, 29, 36) and develops
without an increased collagen fraction (fibrosis) and
with a normal capillary-to-myocyte ratio (34).
In acute AV block, cardiac output falls to ~65–75%
of the original SR value (5, 25). This reduction is
proportional with the severity of the ensuing bradycar-
dia (3, 26). Less agreement exists in the literature in
regard to the mechanical performance during CAVB;
the first studies (3, 25) described the CAVB dog as a
model for heart failure, whereas later studies reported
compensated cardiac function in the majority of dogs.
In our experience, improved contractile function at the
IVR has been observed after 6 wk of AV block (5).
In many laboratories, the AV block dog is used to
study ventricular arrhythmias. The response of the
dogs to interventions (e.g., drugs) is dependent on the
duration of AV block, which is reproducible after 2–3
wk of CAVB (35), suggesting that electrical adapta-
tions are completed within this time period. Electrical
remodeling consists of an increased interventricular
dispersion (34), which has been related to ventricular
arrhythmias, more specifically torsade de pointes (31,
33, 34).

Methodological considerations. For this study, we
were interested in 1) the time course of the structural
adaptation process of both ventricles after CAVB, 2)
the comparison of this process in time with mechanical
and electrophysiological adaptations, and 3) changes at
the executor site of the RAS system, that being the AT1
receptor. Data from the RV are difficult to obtain echocar-
diographically and with the MRI technique are lim-
ited to SR dogs (20). To our knowledge, this is the first
study describing the structural adaptations of the RV
over time.

Time course of structural and functional changes in the CAVB dog. Including the additional time points at 2 and 10 days after CAVB, we were able to demonstrate the quickness by which biventricular hypertrophy evolves. The clear increase in LV mass after 2 days of CAVB (Fig. 4) is in contrast to other data (25, 36) in which the hypertrophy became evident after 10–18 days and clearly manifested between 3 and 7 mo. Whether the RV behaves in a similar time fashion is less clear. Imaging the RV in dogs still is complex due to its position in the thorax. This is most probably the reason that the increase in RV mass as measured with MRI after CAVB was somewhat less compared with that as assessed in autopsied animals (34). Still (Figs. 1, 3, and 4), this remodeling process of both ventricles seems to stabilize after 14–21 days. At least, the majority in growth (90% completion) is seen within 14 days.

In both ventricles, the cardiac mass-to-EDV ratio at chronic CAVB is similar to that in SR, implicating eccentric hypertrophy. This ratio (often used as an indicator for ventricular dilatation) decreases from 1.6 to 1.13 g/ml in dogs with heart failure (6, 14).

Other canine models of volume overload and hypertrophy. Other models of LV overload, such as mitral valve regurgitation (MVR), have reported lower or similar structural adaptations: LV mass increases to 5.0–5.6 g/kg (19, 22, 37, 38). In MVR, the time course is much slower; after 3 wk, only half of the total growth (±10g) has taken place, and it takes ~9 wk before a steady state in LV mass is reached (19). Right-sided changes in mass are absent (37) or not addressed in these articles.

Solitary RV volume overload is not often used in dogs. In one model, a connection was made between the right atrium and the pulmonary artery (16). The RV WT increased by 35% after 30 days and the RV-to-body weight ratio increased to ±2.1 g/kg (16), which is somewhat lower than the observed changes in CAVB.

Creation of an arteriovenous shunt is an example of volume overload that results in biventricular hypertrophy. The LV mass reaches similar or higher values as that in CAVB, ranging from 5.8 to 6.6 g/kg (18, 22), whereas the RV increased to ±2.2 g/kg (18, 22). Similar to our observations, the growth in mass is mainly due to an increase in length of the LV cavity (22) without an increased LV end-diastolic WT. This increase in base-to-apex length was first documented after 2–4 wk (22), suggesting a slower adaptation rate. To our knowledge, information about RV end-diastolic WT in AV shunt has not been reported.

Both MVR and AV shunt canine models lack data to make a full temporal comparison of development of hypertrophy. Still, it seems plausible to say that vol-

Fig. 6. Angiotensin type 1 (AT1) receptor mRNA-to-glyceraldehyde-3-phosphate dehydrogenase (GAPDH) ratio in dogs. There was a similar level of AT1 receptor mRNA expression in the LV and RV of SR dogs (hatched bars). After CAVB (open bars), there was an increase in AT1 receptor mRNA expression in the RV.
Differential Ventricular Remodeling in the CAVB Dog

H2888

Volume overload alone does not explain the rapid time frame of growth in CAVB. When we speculate about other possible causes, we infer that 1) volume overload in CAVB may result in higher (differential) ventricular wall stresses and by that in higher neurohumoral responses, or 2) the prolonged diastolic interval creates more time for growth. Part of the electrical adaptation in MVR and AV shunt is an increase in heart rate.

Background of hypertrophy. The hypertrophy is initiated by mechanical factors and thereafter amplified by neurohumoral factors, such as adrenergic stimuli, RAS, endothelin, and insulin-like growth factor.

In the present study, we restricted ourselves to the effect of CAVB on AT1 receptor mRNA expression, because ANG II is the acting factor in the RAS and so far all its major effects are regulated via the AT1 receptor (13). A previous study (34) from our group showed a temporarily increase in ANG II plasma levels after CAVB creation, which were normalized at 6 wk of CAVB. In the canine heart, ANG II is derived from different sources: plasma or local synthesis by either angiotensin-converting enzyme or chymase from either locally or plasma-derived angiotensinogen (6, 17, 35).

In agreement with Lee et al. (17), SR dogs had a similar ventricular AT1 receptor mRNA expression. In dogs with CAVB, the RV AT1 receptor mRNA increased compared with SR, which could be an explanation for the observed difference in degree of hypertrophy of the RV. Moreover, the increase in AT1 receptor shows an important role for the RAS system in the development of the hypertrophy after CAVB, although other factors cannot be ruled out.

An equal or upregulated AT1 receptor mRNA expression is in contrast to dogs with volume overload due to MVR (6, 27) and dogs with right-sided hypertrophy after pulmonary banding and tricuspidal insufficiency (17), in which the AT1 receptor mRNA content decreased. This difference in AT1 receptor response could be due to differences in models and/or compensated hypertrophy in CAVB versus heart failure.

Also, in patients with heart failure, the density of AT1 receptors was decreased (1, 11), and the lowest values were found in tissue of patients with the worst function (1). The noninfarcted region of the heart in these patients showed an increase in the AT1 receptor (21). When speculating, we hypothesize that AT1 receptors are upregulated in compensated hypertrophy and reduced in heart failure.

Long-term electrophysiological adaptations. We observed a temporal increase in Q-T time during IVR, which reached a maximum ~2–3 wk after AV block (Table 3). Similar results were obtained when the CL and activation sequence were controlled by pacing from the RV endocardial electrode (Fig. 4), indicating that this increase in repolarization time represents true electrical remodeling. The Q-T time increased more during the paced rhythm (±10% IVR vs. ±20% at 1,000 ms), which is most probably related to sequential activation of the RV and LV. The paced Q-T increase of 18% is well in line with serial measurements performed during acute and chronic AV block in anesthetized dogs (34). Q-T time is a global reflection of repolarization, which in anesthetized dogs shows the best correlation with LV APD having an equation close to unity (31). Therefore, the increase in Q-T time is most probably due to the changes in repolarization of the LV. Both in vivo and at a cellular level, we (32, 34) have demonstrated that the RV APD increases less than the LV APD in CAVB dogs (increased dispersion). This is despite the fact that the RV hypertrophy is more pronounced, suggesting that hypertrophy is not the sole contributor to electrical remodeling.

Hypertrophy is linked with a prolonged repolarization and an increased incidence of ventricular arrhythmias and sudden cardiac death in patients (9, 10, 12, 39). These risks are not restricted to (severe) pathological circumstances in which heart failure is present but also occur in physiological states, such as in the heart of endurance athletes with compensated hypertrophy (23) or as described in this animal model with improved inotropic performance (maximal LV rise in pressure over time) at slow rates (5).

Investigations combining information about structural, functional, and electrical measurements are relatively scarce and often restricted to observations related to the increased sensitivity to (pacing induced) arrhythmias after interventions, such as ischemia or drugs (2, 15). Moreover, exact information concerning the sequence and nature of the time-related electrophysiological process in hypertrophy are lacking. In this study, we showed that the increase in Q-T time parallels the process of hypertrophy and mechanical adaptation. Whether they are caused by similar signaling pathway or different pathways has yet to be elucidated using prevention or regression studies, in which AT1 receptor blockade should be the first to be tested.

Technical limitations. With regard to MR measurements, the determination of the RV size and WT is not easy. Still, based on the similar outcome of the repetitive measurements in SR and the correlation with the autopsy data, we are confident that the MRI accurately described the time process of growth. The quantitative difference between the automatic and the manual WT measurements is due to the inclusion of papillary muscles in the former method.

The possible role of the shifting activation patterns of the IVR during the day has not been assessed. Changing the ventricular activation pattern by LV free wall pacing has been reported to result in an increase in LV mass at the region distant from the electrode, which took ~3 mo before completion. In contrast, at the pacing site wall thinning was found (30). In our data, the LV wall thickness at end systole increased homogeneously, indicating that activation did not influence the process of hypertrophy.

In conclusion, electrical, mechanical, and structural adaptation processes after a sudden bradycardia-induced volume overload are rapid and parallel. Within 3 wk, all studied processes have reached a plateau. The degree of hypertrophy was greater in the RV, which was associated with an increase in AT1 receptor mRNA expression in this ventricle after CAVB.
The authors thank the people at the MRI laboratory for help and experience, especially Guillaume Thelissen and Mark Geerlings. Furthermore, we thank 1) the Department of Diagnostic Radiology, Leiden University Medical Centre, Leiden, The Netherlands, for the use of the MASS program; 2) Drs. A. Moorman and R. Lekanne Deprez, Department of Anatomy and Embryology, University of Amsterdam, Amsterdam, The Netherlands, for technical advice; and 3) Drs. J. Smits and M. Blankensteijn, Department of Pharmacology, University of Maastricht, The Netherlands, for assistance in obtaining the molecular probes. We also thank Dr. Lindpaintner for providing the AT1 receptor primers.
