Bundgaard, Henning, Keld Kjeldsen, Karen Suarez Krabbe, Gerrit van Hall, Lene Simonsen, Jesper Qvist, Christian Muff Hansen, Kirsten Møller, Lise Fonsmark, Per Lav Madsen, and Bente Klarlund Pedersen. Endotoxemia stimulates skeletal muscle Na\textsuperscript{+}-K\textsuperscript{+}-ATPase and raises blood lactate under aerobic conditions in humans. Am J Physiol Heart Circ Physiol 284: H1028–H1034, 2003.—First published November 21, 2002; 10.1152/ajpheart.00639.2002.—We assessed the hypothesis that the epinephrine surge present during sepsis accelerates aerobic glycolysis and lactate production by increasing activity of skeletal muscle Na\textsuperscript{+}-K\textsuperscript{+}-ATPase. Healthy volunteers received an intravenous bolus of endotoxin or placebo in a randomized order on two different days. Endotoxia induced a response resembling sepsis. Endotoxia increased plasma epinephrine to a maximum at $t = 2$ h of $0.7 \pm 0.1$ vs. $0.3 \pm 0.1 \text{ nmol/l} (P < 0.05, n = 6–7)$. Endotoxia reduced plasma K\textsuperscript{+} reaching a nadir at $t = 5$ h of $3.3 \pm 0.1$ vs. $3.8 \pm 0.1 \text{ nmol/l} (P < 0.01, n = 6–7)$, followed by an increase to placebo level at $t = 7–8$ h. During the declining plasma K\textsuperscript{+}, a relative accumulation of K\textsuperscript{+} was seen reaching a maximum at $t = 6$ h of $8.7 \pm 3.8 \text{ mmol/\text{kg}} (P < 0.05)$. Plasma lactate increased to a maximum at $t = 1$ h of $2.5 \pm 0.5$ vs. $0.9 \pm 0.1 \text{ mmol/l} (P < 0.05, n = 6)$ in association with increased release of lactate from the legs. These changes were not associated with hypoperfusion or hypoxia. During the first 24 h after endotoxin infusion, renal K\textsuperscript{+} excretion was $27 \pm 7 \text{ mmol, i.e.}, 58\%$ higher than after placebo. Combination of the well-known stimulatory effect of catecholamines on skeletal muscle Na\textsuperscript{+}-K\textsuperscript{+}-ATPase activity, with the present confirmation of an expected Na\textsuperscript{+}-K\textsuperscript{+}-ATPase-induced decline in plasma K\textsuperscript{+}, suggests that the increased lactate release was due to increased Na\textsuperscript{+}-K\textsuperscript{+}-ATPase activity, supporting our hypothesis. Thus increased lactate levels in acutely and severely ill patients should not be managed only from the point of view that it reflects hypoxia.

K\textsuperscript{+} homeostasis; sepsis; glycolysis

Patients with trauma or sepsis hyperlactacidemia are usually managed from the point of view that it reflects anaerobic glycolysis caused by tissue hypoxia. However, it has been suggested that increased activity of skeletal muscle Na\textsuperscript{+}-K\textsuperscript{+}-ATPase caused by the epinephrine surge present in such patients causes aerobic glycolysis and lactate production (12, 13), i.e., the production of 2 mol ATP by glycolysis compared with 38 mol by complete oxidation of 1 mol of glucose may not be a consequence of anaerobic conditions, but an effect linked to the Na\textsuperscript{+}-K\textsuperscript{+}-ATPase activity. This hypothesis is favored by several observations. First, a 46% increase in Na\textsuperscript{+}-K\textsuperscript{+}-ATPase activity has been observed in extensor digitorum longus muscles from septic rats (22). Second, in well-oxygenated skeletal muscles, increased Na\textsuperscript{+}-K\textsuperscript{+}-ATPase activity induced by monensin (12), epinephrine, amylin (14), or insulin (21) leads to increased lactate production, and, on the other hand, inhibition of the Na\textsuperscript{+}-K\textsuperscript{+}-ATPase by ouabain or reduced extracellular K\textsuperscript{+} concentration reduces lactate production (14). Third, increased skeletal muscle Na\textsuperscript{+}-K\textsuperscript{+}-ATPase activity is induced by increased catecholamine levels that are present in trauma and sepsis. Fourth, a positive correlation between plasma lactate and plasma catecholamine concentrations has been observed and a reduction or blockage of hyperlactacidemia can be achieved by adrenergic blockade (for a review, see Ref. 13). If an increased catecholamine level is responsible for a part of the increase in blood lactate level in traumatized or septic patients, this has to be taken into account because it may be present in patients after compromised perfusion and tissue oxygen delivery have been normalized. It is well known that the catecholamine stimulation of the skeletal muscle Na\textsuperscript{+}-K\textsuperscript{+}-ATPase is achieved via $\beta_2$-adrenoceptors (2), and that increased activity of the Na\textsuperscript{+}-K\textsuperscript{+}-ATPase, caused by pumping Na\textsuperscript{+} out and K\textsuperscript{+} into the cell in a 3:2 relationship, leads to increased cellular K\textsuperscript{+} uptake (2). This may lead to hypokalemia, which is actually a frequent finding at admission of severely ill patients (5, 19). Furthermore, a catecholamine-induced increase in Na\textsuperscript{+}-K\textsuperscript{+}-ATPase activity may not only induce skeletal muscle K\textsuperscript{+} uptake, but catecholamines...
may also via α- and β-adrenoceptors alter renal tubular Na⁺-K⁺-ATPase activity (11) and thus affect renal K⁺ excretion.

Several observations favoring the hypothesis that catecholamine stimulation of Na⁺-K⁺-ATPase secondary leads to lactate production, comes from studies of isolated cells and animal models, whereas studies in humans have not been reported. Therefore, in the present study, we assessed the effect in humans of endotoxin on the K⁺ homeostasis and lactate concentration changes after infusion of endotoxin and at least 14 days apart after placebo administration immediately available. The volunteers were studied in an intensive care unit setting under the continuous supervision of a cardiologist and an anesthesiologist. Isotonic saline solution was infused. From 8 AM until 8 PM, noradrenaline was administered continuously. Furthermore, the subjects were monitored with standard clinical equipment immediately available. The volunteers were studied in an intensive care unit setting under the continuous supervision of a cardiologist and an anesthesiologist. Isotonic saline solution was infused. From 8 AM until 8 PM, noradrenaline was administered continuously. Furthermore, the subjects were monitored with standard clinical equipment immediately available.

Volunteers

Eight healthy young volunteers (21–25 yr, 77 ± 3 kg body wt) were studied. None of the subjects had a history of medical problems, and physical examination revealed no abnormalities. Blood analyses showed normal hemoglobin, white blood cell count (WBC), WBC differential count, C-reactive protein (CRP), and blood glucose as well as normal kidney function (urea and creatinine), normal liver function (alanine aminotransferase, alkaline phosphatase, and lactate dehydrogenase), normal coagulation system (activated partial thromboplastin time, antithrombin III, prothrombin time, and international normalized ratio (INR)), and normal thyroid-stimulating hormone. All had a normal ECG. The volunteers did not use any medication, and they did not have any febrile illness in the 2 wk preceding the study.

Study Design

The presently used study design has previously been described in detail (18). In brief, the study was performed in an intensive care unit setting under the continuous supervision of an anesthesiologist, with emergency and resuscitation equipment immediately available. The volunteers were studied after endotoxin infusion and at least 14 days apart after placebo infusion. The sequence endotoxin/placebo was randomly chosen. Because of the obvious symptomatic (temperature and blood pressure) changes after infusion of endotoxin, neither the volunteers nor the staff was blinded to the study protocol.

The volunteers fasted overnight before endotoxin or placebo administration. Rectal temperature was recorded continuously. Furthermore, the subjects were monitored with respect to blood pressure (by a radial artery catheter) and heart rate. A femoral vein was catheterized for blood sampling. Isotonic saline solution was infused. From 8 AM until 8 PM, isotonic glucose (50 mg kg⁻¹ h⁻¹) was continuously infused. Subjects were given an intravenous bolus of endotoxin on the K⁺ side of the cell membrane, which was automatically analyzed enzymatically with lactate dehydrogenase (Cobas Fara, Roche; Basel, Switzerland). The volunteers were encouraged to empty the bladder just before endotoxin was injected, and urine was collected for the period t = 0–24 h.

Analyses

Catecholamines. Blood samples for measurements of epinephrine and norepinephrine were drawn into ice-cold glass tubes containing EGTA glutathione. Plasma was stored at −80°C until analyzed by high-performance liquid chromatography (Hewlett-Packard; Waldbronn, Germany) with electrochemical detection as previously described (10).

Tumor necrosis factor-α. Blood samples were drawn into ice-cold tubes containing EDTA and trasylo and then spun immediately at 2,200 g for 15 min at 4°C. Plasma was stored at −80°C until analyzed. Tumor necrosis factor-α (TNF-α) was determined with the use of an ELISA kit (detection limit 0.5 pg/ml, R&D Systems; Minneapolis, MN). According to the manufacturer, the TNF-α ELISA kits are insensitive to the addition of recombinant forms of the soluble receptor, and the measurements therefore correspond to both soluble and receptor-bound cytokine. All cytokine determinations were run as duplicates, and mean values were calculated.

Clinical chemistry tests. Standard laboratory procedures were employed. Urine and plasma K⁺ were measured with a potentiometer (model 917, Hitachi). Only plasma K⁺ measurements obtained from the Hitachi 917 at t = 24 and 32 h are given in RESULTS.

Leg blood flow. The femoral arterial leg blood flow (LBF) was calculated as t = 0, and each hour until t = 8 h with the ultrasound Doppler technique, as previously validated (25). An ultrasound Doppler (model CFM 800; Vingmed Sound; Horton, Norway) equipped with an annular phased-array transducer probe 11.5-mm diameter (Vingmed Sound) operating at an imaging frequency of 7.5 MHz and the variable Doppler frequencies of 4.0–6.0 MHz (high-pulsed repetition frequency mode 4–36 kHz was used) (25).

Calculations and Statistics

K⁺ uptake in one leg was calculated as the arteriovenous plasma K⁺ difference multiplied by leg plasma flow [LBF × (1 − hematocrit)]. Lactate release from one leg was calculated as the venoarterial plasma lactate difference multiplied by LBF. Accumulated K⁺ uptake was calculated as the sum of K⁺ uptake each hour during the period of interest. Difference in accumulated K⁺ uptake between the two groups was calculated as the accumulated K⁺ uptake after placebo subtracted from the accumulated K⁺ uptake after endotoxin. Statistical significance between measurements obtained at two or more different time points after placebo and after endotoxin (paired design) was ascertained by two-way repeated-measures ANOVA with SigmaStat for Windows version 2.03 (SPSS). The two factors were treatment (placebo vs. endotoxin) and time. After a statistically significant treat-
Infusion of endotoxin significantly increased the plasma epinephrine concentration to a maximum at $t = 2\ h$ of $0.7 \pm 0.1\ \text{versus } 0.3 \pm 0.1\ \text{nmol/l (P < 0.05, n = 6–7)}$ (Fig. 2) whereas only a tendency to an increase was seen in the plasma norepinephrine level (data not shown).

**Plasma K⁺**

Infusion of endotoxin significantly reduced femoral venous plasma K⁺, reaching a nadir at $t = 5\ \text{h}$ of $3.3 \pm 0.1$ compared with $3.8 \pm 0.1\ \text{mmol/l after placebo infusion (P < 0.01, n = 6–7)}$ (Fig. 3A). After the nadir was reached, venous plasma K⁺ increased to the level measured after placebo infusion after another 2–3 h. Similar changes were seen in arterial plasma K⁺. At $t = 8\ \text{h}$ the initial plasma K⁺ level was reached and plasma K⁺ remained stable for the next 24 h in both groups. At $t = 24$ and 32 h, venous plasma K⁺ values were

![Fig. 1. Plasma tumor necrosis factor-α (TNF-α) concentrations measured in 8 healthy human subjects after infusion of endotoxin or placebo at time ($t$) = 0. Statistics: with the use of two-way repeated-measures (RM) ANOVA (see MATERIALS AND METHODS), the plasma TNF-α level was found to be statistically significantly increased after endotoxin compared with placebo. Geometric means and 95% confidence intervals are indicated.](http://ajpheart.physiology.org/)

![Fig. 2. Plasma epinephrine concentrations measured in 8 healthy human subjects after infusion of endotoxin or placebo at time ($t$) = 0. Statistics: with the use of two-way RM ANOVA (see MATERIALS AND METHODS), the plasma epinephrine level was found to be statistically significantly increased after endotoxin compared with placebo. Values are means ± SE.](http://ajpheart.physiology.org/)
there was a reduced loss of $K^+$ with the increased LBF. This indicates that the plasma $K^+$ endotoxin infusion. On the basis of arteriovenous arm and venous plasma $K^+$ differences and LBF measurements obtained each hour after endotoxin and placebo infusions, the accumulated transport of $K^+$ to or from the leg could be calculated (Fig. 4). After placebo infusion, the accumulated $K^+$ exchange across the leg showed a constant loss of $K^+$ from the leg (linear regression analysis; $\alpha = -1.75 \pm 0.13 \text{ mmol K/h}$, $r^2 = 0.95$, $P < 0.01$). However, after endotoxin infusion, the loss of $K^+$ from the leg was reduced within the first hours. Thus the difference in accumulated $K^+$ (accumulated $K^+$ after endotoxin placebo) showed a gradual increase reaching a maximum after 6 h of $8.7 \pm 3.8 \text{ mmol per leg}$ ($P < 0.05$) (Fig. 4).

Renal $K^+$ Excretion

Urine volumes for the first 24 h after infusions were similar after endotoxin infusion (2,869 ± 253) and placebo infusion (2,788 ± 252 ml) ($P > 0.7$, $n = 8$). After endotoxin infusion urine $K^+$ concentration was $27 \pm 3$ compared with $18 \pm 2 \text{ mmol/l}$ after placebo infusion, i.e., an increase of $50\%$ ($P < 0.05$, $n = 8$). Thus during the first 24 h after endotoxin infusion, the total renal $K^+$ excretion was $27 \pm 7 \text{ mmol}$, i.e., $58\%$ ($P < 0.01$) higher compared with placebo. After endotoxin and placebo were $3.8 \pm 0.1$ vs. $3.7 \pm 0.1 \text{ mmol/l}$ ($P = 0.8$, $n = 8$) and $3.7 \pm 0.1$ vs. $3.7 \pm 0.1 \text{ mmol/l}$ ($P < 0.6$, $n = 8$), respectively.

$K^+$ Exchange Across Leg

After placebo, venous plasma $K^+$ was slightly higher than arterial plasma $K^+$, which reflects a small $K^+$ loss from the resting leg (Fig. 3A and B). Until $t = 5$ h, the arteriovenous plasma $K^+$ difference was numerically higher after placebo compared with endotoxin, reaching a maximum at $t = 4$ h of $-0.2 \pm 0.1$ versus $0.0 \pm 0.1 \text{ mmol/l}$ ($P < 0.05$, $n = 8$) (Fig. 3B). In combination with the increased LBF this indicates that until $t = 5-6$ h there was a reduced loss of $K^+$ from the leg after endotoxin infusion. On the basis of arteriovenous plasma $K^+$ differences and LBF measurements obtained each hour after endotoxin and placebo infusions, the accumulated amount of $K^+$ per leg in 8 healthy human subjects after infusion of endotoxin or placebo at $t = 0$. Statistics: with two-way RM ANOVA (see MATERIALS AND METHODS), the arteriovenous plasma $K^+$ difference level was found to be statistically significantly different after endotoxin compared with placebo. Values are means ± SE.
measuring >97% and no significant differences in venous oxygen saturation was observed. These observations, taken together with the observed increase in LBF, indicate that changes in blood lactate concentrations were not associated with reduced tissue oxygen supply. Moreover, the increase in plasma lactate was associated with a significant increase in plasma pH from 7.39 ± 0.01 to a maximum of 7.43 ± 0.01 (P < 0.05, n = 8) at t = 5 h, whereas no changes were seen after placebo infusion. The increase in pH may have been related in part to hyperventilation because a decrease in PCO₂ after endotoxin infusion was seen, reaching a nadir at t = 5 h of 4.7 ± 0.1 compared with 5.3 ± 0.1 kPa (P < 0.05, n = 7–8) after placebo.

**DISCUSSION**

The present study demonstrates that in healthy humans endotoxemia leads to hypokalemia and a relative accumulation of K⁺ in the legs associated with increases in plasma catecholamines and plasma lactate concentrations without hypoxia, signs of hypoperfusion or reduced pH. In this model, endotoxin induced clinical, hemodynamic, immunologic, and hormonal responses resembling the responses seen in patients with sepsis, which ensures clinical relevance of the obtained results.

In endotoxic rats, an increase in the activity of the pool of skeletal muscle Na⁺-K⁺ pumps has been shown without an associated increase in expression of messenger RNA for the α- or the β-subunits of the pump or increasing Na⁺-K⁺ pump number (22). Thus the present study supports the hypothesis that endotoxin exposure increases skeletal muscle Na⁺-K⁺-ATPase activity (13) as assessed by a significant decrease in plasma K⁺ and a relative increase in K⁺ uptake in the leg induced by increased levels of catecholamines. The present observation of hypokalemia after endotoxin exposure has previously been observed in cows (23). We observed a constant loss of K⁺ from the muscles in the placebo group. This is in accordance with previous studies in humans showing that at rest venous plasma K⁺ is higher than arterial plasma K⁺ (6, 9, 15, 17, 27). This may be explained by clearance of K⁺ into the muscles for buffering after a meal, followed by a gradual loss of K⁺ back to the extracellular fluid volume (ECV) and eventually excretion by the kidneys. After endotoxin infusion the plasma lactate level remained elevated after maximum changes in the K⁺ homeostasis and in plasma epinephrine level were seen (Fig. 5A). This observation most likely reflects the variability in the measurements of plasma lactate as also seen in Fig. 5B, but may also reflect that plasma epinephrine level did not completely reach control level during this period (Fig. 2). However, a highly significant increase in plasma lactate of up to 177% was induced by endotoxin and it is of interest that this increase was of same order of magnitude as the insulin-induced ouabain-suppressible increase of 135% observed in humans during stimulation of skeletal muscle Na⁺-K⁺-ATPase by an euglycemic-hyperinsulinemic clamp (21). However, it should be noted that in the present study neither the plasma lactate increase, nor the plasma K⁺ decrease, was due to an insulin-induced Na⁺-K⁺-ATPase stimulation because no significant differences in plasma insulin concentrations were observed after endotoxin infusion compared with placebo. The presently observed indications of increased skeletal muscle Na⁺-K⁺-ATPase activity during endotoxemia are at variance with a report of no difference in cellular ⁸⁶Rb uptake in soleus muscle from rats treated with *Salmonella enteritidis* endotoxin (16). However, the soleus muscles were examined after excision and incubation in endotoxin-free buffers. Therefore, an ongoing effect of endotoxin could not be expected. This illustrates one of the possible pitfalls in in vitro assays compared with in vivo studies.

Assuming a total body skeletal muscle weight of ~40% of body weight, a skeletal muscle mass in one leg drained by the femoral vein of 10% of body weight (20) and a skeletal muscle K⁺ content of ~75% of total body K⁺ content of ~3,500 mmol (3) the accumulated difference in leg K⁺ content in each leg 6 h after endotoxin and placebo infusions of ~9 mmol, corresponds to ~1
mmol/kg K⁺ skeletal muscle, i.e., 1.2%. Furthermore, assuming similar skeletal muscle K⁺ accumulation throughout the body, a total body skeletal muscle K⁺ accumulation of ~35 mmol at t = 6 h can be calculated after endotoxin infusion compared with after placebo infusion. The magnitude of this relative increase in skeletal muscle K⁺ cannot fully be explained by the simultaneous decline in total ECV K⁺ of 8 mmol [ECV (20% of body wt) × plasma K⁺ decrease (~0.5 mmol)]. This indicates that the K⁺ changes were to a certain extent the result of K⁺ shifts between ECV and skeletal muscles, but other organs, or regulatory mechanisms, e.g., temporal changes in renal K⁺ excretion, may also have been involved. After the plasma K⁺ nadir at t = 5 h, a gradual increase in plasma K⁺ was observed with an increased venoarterial K⁺ difference compared with before the nadir was reached (Fig. 3A). This indicates that the relative skeletal muscle K⁺ accumulation ceased at t = 5–6 h and was followed by an increased loss of K⁺ to the extracellular phase. Thus as presently as well as previously seen (18) the major effects of a single endotoxin bolus seems to vanish after ~5 h. Thus the study shows the initial effects of endotoxin on the extrarenal K⁺ homeostasis, but the study design does not allow further assessment of the clinical situation with the septic patient with ongoing endotoxin production. It is important to notice that the shivering observed during the increase in temperature represents muscle work. During muscle work, the excitation-contraction sequence leads to a net loss of K⁺ to the extracellular space (26). Thus shivering per se would have been expected to increase plasma K⁺. In contrast, we observed a decline in plasma K⁺, which can be explained by the catecholamine-induced stimulation of the Na⁺-K⁺-ATPase activity. It was ensured that the plasma K⁺ increase after the nadir at t = 5 h was not a result of rhabdomyolysis as indicated by unaltered plasma myoglobin concentrations.

To the best of our knowledge, the observed significant increase in renal K⁺ excretion has not previously been reported. It should be noted that the higher K⁺ excretion after endotoxin infusion was measured for the 24-h period after the infusions, whereas the skeletal muscle K⁺ content changes were assessed after the initial 6 h. The combination of a reduction in skeletal muscle K⁺ loss and an increase in renal K⁺ excretion would be expected to reduce plasma K⁺ or involve K⁺ loss from other compartments or organs. However, it should be stressed that during the period of increased renal K⁺ excretion (t = 0–24 h) skeletal muscle K⁺ underwent a biphasic change: first, a relative accumulation, followed by an increased K⁺ loss and at t = 24 h, skeletal muscle K⁺ may actually have been reduced after endotoxin infusion compared with placebo. This suggestion is supported by the observation of a tendency to lower plasma K⁺ concentrations at t = 24–32 h after endotoxin infusion.

Catecholamine stimulation of proximal tubule α-adrenoceptor increases Na⁺-K⁺-ATPase activity, whereas a decrease is obtained by β-adrenoceptor stimulation and dual stimulation may counterbalance each other (11). A micropuncture study showed that epinephrine reduces renal K⁺ excretion (4) and a study using isolated kidneys showed that norepinephrine also reduces K⁺ excretion (1). Thus it is most likely that the presently observed increase in renal K⁺ excretion after endotoxin infusion may have been the combined outcome of a reduced renal K⁺ excretion due to increased levels of catecholamines but at the same time an increased excretion induced by increased ACTH and cortisol concentration levels.

In vitro studies have shown that endotoxin via increased levels of IL-6 and TNF-α reduce hepatocyte (7, 8, 28) and thyroid cell (24) Na⁺-K⁺-ATPase activity, respectively. Such changes would tend to increase plasma K⁺. Moreover, these results indicate that the numerous responses seen in sepsis, i.e., inflammatory, hormonal, metabolic, and hemodynamic changes may induce different or even opposite changes in different organs.

Taken together, the present study supports the hypothesis that in humans blood lactate level may increase under aerobic conditions. The combination of the well-known stimulatory effect on skeletal muscle Na⁺-K⁺-ATPase activity of catecholamines and the present confirmation of the correspondingly expected Na⁺-K⁺-ATPase-induced decline in plasma K⁺ suggests that the increase in skeletal muscle lactate release was due to increased Na⁺-K⁺-ATPase activity. The findings also point to the importance of the K⁺ homeostasis. It should be noted that the presently observed effect on the K⁺ homeostasis is not supposed to be a specific response to endotoxemia, but may be present in general in acutely and severely ill patients with a stress response. The present study indicates that in such patients hypokalemia may not necessarily be interpreted as K⁺ deficiency, as it may reflect (temporarily) increased muscle K⁺ uptake, but on the other hand it is important to compensate for an increased renal K⁺ excretion.

We thank consulting biostatistician Gordon Doig (Royal North Shore Hospital, St. Leonards, Sydney, Australia) for valuable statistical assistance.

The study was supported in part by the Emil C. and Inger Hertz Foundation.
