Cerebral artery responses to pressure and flow in uremic hypertensive and spontaneously hypertensive rats. Am J Physiol Heart Circ Physiol 284: H1212–H1216, 2003; 10.1152/ajpheart.00644.2002.—Impaired cerebral blood flow autoregulation is seen in uremic hypertension, whereas in nonuremic hypertension autoregulation is shifted toward higher perfusion pressure. The cerebral artery constricts in response to a rise in either lumen pressure or flow; we examined these responses in isolated middle cerebral artery segments from uremic Wistar-Kyoto rats (WKYU), normotensive control rats (WKYC), and spontaneously hypertensive rats (SHR). Pressure-induced (myogenic) constriction developed at 100 mmHg; lumen flow was then increased in steps from 0 to 98 μl/min. Some vessels were studied after endothelium ablation. Myogenic constriction was significantly lower in WKYU (28 ± 2.9%) compared with both WKYC (39 ± 2.5%, \(P = 0.035\)) and SHR (40 ± 3.1%, \(P = 0.018\)). Flow caused constriction of arteries from all groups in an endothelium-independent manner. The response to flow was similar in WKYU and WKYC, whereas SHR displayed increased constriction compared with WKYU (\(P < 0.001\)) and WKYC (\(P < 0.001\)). We conclude that cerebral myogenic constriction is decreased in WKYU, whereas flow-induced constriction is enhanced in SHR.

Myogenic tone; flow-induced constriction; myograph

Uremia is associated with stroke, particularly hemorrhagic stroke, in animals (25) and humans (10). Although raised blood pressure often contributes to this risk (11, 15), other factors may be important. In the stroke-prone hypertensive rat, uremia develops due to hypertension associated with glomerulosclerosis (9), followed by impaired cerebral autoregulation, before stroke (26, 28). Humans with renal failure have increased cerebral blood flow with decreased vasodilatory capacity (16). Therefore, it is possible that an abnormality of cerebral vascular autoregulation, characterized by inadequate constriction, results from uremia.

Conversely, hypertensive (nonuremic) animals (1, 21) and humans (17, 29) show vascular adaptation with a shift of cerebral blood flow autoregulation toward higher levels of arterial pressure. The increased vascular resistance is largely due to greater constriction, rather than to smooth muscle hypertrophy (23), and maintains constancy of blood flow despite systemic hypertension.

Cerebral vascular resistance is to a major extent determined by the degree of contraction of larger proximal arteries such as the middle cerebral artery (7), unlike other vascular beds, in which most of the resistance to blood flow occurs in arteries below ~200 μm diameter (4, 20). Large artery tone therefore regulates cerebral microvascular pressure (1, 7), and it has been suggested that this mechanism protects more distal thin-walled intracranial blood vessels (8). If this is the case, then enhanced proximal cerebral vascular resistance may guard against stroke in chronic nonuremic hypertension, whereas inadequate vascular constriction seen in uremic hypertension might predispose to stroke.

Because cerebral artery tone increases in response to a rise in either lumen pressure (22) or flow (2, 18), the changes in cerebral autoregulation in uremic and nonuremic hypertension might conceivably reflect changes in either of these processes. We hypothesized that uremia impairs the response to pressure and/or flow in cerebral arteries. Using Wistar-Kyoto (WKY) rats, we studied isolated middle cerebral artery segments from the subtotal nephrectomy rat model of uremic hypertension (WKYU), comparing them with sham-operated normotensive control vessels (WKYC) and spontaneously hypertensive rat vessels (SHR).

MATERIALS AND METHODS

Animals. All procedures had the prior approval of the Home Office (project license no. 70/5014) and were performed in accordance with the Animals Scientific Procedures Act of 1986. Male WKY and SHR (12–14 wk old) were obtained from Harlan. General anesthesia was induced for both stages of nephrectomy by an intramuscular injection of 1 ml/kg body wt Hypnorm (0.315 mg/ml fentanyl citrate plus 10 mg/ml fluanisone; Janssen-Cilag), followed by an intraperitoneal injection of 2.5 mg/kg diazepam (CP Pharmaceuticals). Postoperative analgesia was provided by subcutaneous injection of buprenorphine (50 μg/kg, Schering-Plough). Left subtotal nephrectomy was performed through a midline abdominal incision, removing approximately three-fourths of the renal mass. A total right nephrectomy was performed through a flank incision 1 wk later. WKY and SHR animals underwent sham surgery in which the appropriate kidney was removed. stripped of its capsule only. Animals were maintained for ~3 mo during which WKYU and SHR were pair fed with their WKYU partners. Approximately 5 days before death, animals were placed in a metabolic cage for a timed overnight urine collection. Under halothane anesthesia (Concord Pharmaceuticals), an abdominal aortic catheter (0.61 mm outer diameter and 0.28 mm inner diameter, Sams Portex) was then inserted retrogradely through the femoral artery, heparinized, and exteriorized through the skin at the nape of the neck (13). Two to three days later, conscious blood pressure was measured with a pressure transducer (model 60-3003, Harvard Apparatus). Blood was drawn for analysis, and the animal was euthanized by cervical dislocation. The brain was removed immediately and placed in ice-cold physiological saline solution (PSS). A single artery was studied from each rat on the day of death; the cerebral hemisphere was pinned to a Silastic base within a petri dish containing cold PSS, and the middle cerebral artery was dissected free from surrounding tissue under view of a binocular microscope (Stemi SV6, Zeiss).

Bioclmical and hematological analysis. Plasma and urinary creatinine concentrations were determined by the Jaffé method with the use of a creatinine analyzer (Beckman Coulter). Blood hemoglobin was measured using a $\beta$-hemoglobin photometer (Hemocue).

Drugs and solutions. All chemicals (Sigma-Aldrich) were made up on the day of the experiment in sterile distilled AnaLAR water (Merck). PSS was composed of the following (in mmol/l): 119 NaCl, 4.7 KCl, 25 NaHCO3, 1.17 KH2PO4, 1.17 MgSO4, 2.0 CaCl2, and 5.5 glucose. CaCl2 was added to PSS, which could potentially lose CO2 tension while traversing the proximal tubing system. For this reason, perfusate passed through a 12-cm-long gas-permeable (silicon) tube submersed in the PSS of the myograph chamber immediately before reaching the proximal cannula. This allowed for reequilibration of CO2 between chamber and perfusate. This would minimize the possibility of inadequately equilibrated perfusate causing cerebral constriction because cerebral artery tone is sensitive to pH (27). Control experiments confirmed that when un-gassed bicarbonate buffer was used as perfusate, constriction to flow was observed, further suggesting that flow-induced constriction is due to shear stress and not to alkalinity of the perfusate. Finally, although it is impossible to measure the temperature of the perfusate as it enters the vessel due to the dimensions involved, inadequate heat equilibration would, if present, be expected to cause dilation rather than constriction (5).

Calculations and statistical analysis. Wall shear stress ($\sigma$; in dyn/cm²) was calculated from the equation $\sigma = 4\eta Q/\pi r^3$, where $\eta$ is the viscosity of PSS taken as 0.007 dyn·s·cm⁻¹ (14), $Q$ is the lumen flow rate ($\mu$m³/s), and $r$ is the internal radius ($\mu$m) of the vessel. Myogenic constriction [MC (%)] was calculated from the equation $MC = 100 \times \frac{D_P - D_A}{D_P}$, where $D_P$ is the passive diameter and $D_A$ is the active diameter at 100 mmHg of lumen pressure. Flow-induced constriction [FC (%)] was assessed by the equation $FC = 100 \times \frac{D_P - D_0 + D_f}{D_0}$, where $D_0$ is the diameter with myogenic constriction at zero flow rate and $D_f$ is the diameter at any given flow rate (2). Creatinine clearance [Clcr (ml/min)] was calculated using the equation $Clcr = \frac{Ucr \times V}{Pcr \times t}$, where $Ucr$ is urine creatinine, $Pcr$ is plasma creatinine concentration ($\mu$mol/l), and $V$ is the volume of urine (ml) passed in time t (min).

Values are expressed as the means ± SE. All comparisons were made between three groups: WKYU, WKYC, and SHR. Single-valued variables such as plasma creatinine were compared by one-way ANOVA. A series of measurements, such as the flow-diameter relation, were compared by repeated-measures ANOVA. The Bonferroni correction was applied to all analyses, allowing direct comparison between all combinations of two groups. The significance level was taken as $P < 0.05$.

RESULTS

General information regarding the animals and the cerebral arteries from each group are given in Table 1. Mean arterial pressure was significantly greater in SHR than in WKYU, and WKYU were significantly hypertensive relative to WKYC. Substantial uremia developed in WKYU.

At 100 mmHg of distending pressure and zero lumen flow, WKYU developed significantly less myogenic con-
striction (28 ± 2.9%) compared with WKYC (39 ± 2.5%, \( P = 0.035 \)) and SHR (40 ± 3.1%, \( P = 0.018, n = 17 \) per group). From these, flow responses were successfully studied in 10 animals per group, and flow responses after endothelial ablation in 2–4 animals per group. Assessment of flow responses was abandoned in some arteries due to cannula blockage or passage of an air bubble through the vessel lumen.

Vessel diameter, as assessed by repeated-measures ANOVA across the flow range, was significantly greater in WKYU compared with WKYC (\( P = 0.001 \)) and also significantly greater in WKYC compared with SHR (\( P < 0.01 \)) (Fig. 1).

All arteries constricted to increasing lumen flow (Fig. 1). Flow-induced constriction was evident in arteries even after ablation of endothelium (data not shown). WKYU and WKYC showed similar percent changes in diameter to flow (\( P \) not significant), with constriction at low-flow rates and plateau at higher rates (Fig. 2). SHR exhibited enhanced constriction to flow compared with both WKYU (\( P < 0.001 \)) and WKYC (\( P < 0.001 \)), with progressive constriction over almost the entire flow range (Fig. 2). A similar pattern of response was seen when diameter was plotted against shear stress rather than flow rate (Fig. 3).

**DISCUSSION**

The major findings of this study are that cerebral myogenic constriction is impaired in arteries from WKYU, whereas increased constriction to flow is seen in SHR, compared with normotensive controls.

Pressure-dependent (myogenic) constriction is well described in rat cerebral arteries; at 100 mmHg, WKYC and SHR demonstrated equal response in our study, in keeping with a prior comparison (22). The

crease in diameter when exposed to 100 dyn/cm². The hypertensive rat strain possessing genetically typical arterioles measured under steady-state conditions, in a normotensive state, has been documented. Our finding of the independent response of cerebral arteries to shear stress. This value is very similar to that seen previously in WKY and likewise appears to be endothelium independent. The response of cerebral arteries to large pressure step. However, such pressure increments, in addition to stimulating myogenic contraction, may elicit transient nitric oxide release from rat cerebral artery endothelium (6) and might therefore underestimate myogenic constriction. Further evaluation of stroke-prone SHR cerebral arteries suggested that levels of myogenic tone were normal (12), although the level of uremia, if present, was not reported. Our study is, therefore, the first to establish the degree of cerebral myogenic constriction in uremia, measured under steady-state conditions, in a normotensive rat strain possessing genetically typical arterioles. The finding of substantially decreased tone in WKY compared with WKYC and SHR supports the notion of uremic impairment of myogenic constriction. This might explain the impaired cerebral autoregulation seen in uremia in vivo.

Flow-dependent constriction is known to occur in the rat middle cerebral artery; a previous report (2) established that vessels responded with ~15% decrease in diameter when exposed to 100 dyn/cm² shear stress. This value is very similar to that seen in our WKY and likewise appears to be endothelium independent. The response of cerebral arteries to flow, either in uremia or hypertension, has not hitherto been documented. Our finding of an augmented constriction to flow in SHR is compatible with the observed in vivo pattern of cerebral blood flow autoregulation in SHR (21). If increased constriction to flow is an adaptation to raised blood pressure, rather than a property unique to the SHR cerebral artery, then this adaptation was not present in uremic hypertension.

In addition to the experimental data discussed above, it seems likely, on clinical grounds, that proximal resistance artery inadequacy in the brain results in cerebral overperfusion and microvascular damage. First, in acute hypertensive encephalopathy, there is failure of autoregulatory vasoconstriction with dilation of distal vessels and increased cerebral blood flow (30); fibrinoid necrosis of arterioles leads to cerebral microinfarcts and petechial hemorrhages (3). Second, the cerebral hyperperfusion syndrome may follow cerebral revascularisation by endarterectomy (24) or stent placement (19); newly elevated perfusion pressure overwhelms arteriolar autoregulation, sometimes precipitating intracerebral hemorrhage. Finally, a breakdown of cerebral autoregulation with hyperperfusion may lead to vasogenic cerebral edema in the preeclampsia/eclampsia syndrome (33). It appears reasonable to speculate that dissipation of perfusion pressure early in the course of the cerebral circulation may be necessary to maintain an intact microvasculature; if this fails, and particularly if systemic pressure is high, stroke may occur. Although in (stroke resistant) SHR microvascular pressure is maintained low relative to arterial pressure by a raised cerebral artery resistance (1), similar direct microvascular pressure measurements are lacking in uremia. Such information would be required to confirm whether or not the above reasoning can be applied to uremia.

There was no evidence of stroke in uremic hypertensive rats. This contrasts with the situation in stroke prone SHR. The mean arterial pressure of WKYU was raised compared with WKYC, although was still substantially lower than that of SHR. Because lowering blood pressure in stroke-prone SHR is known to prevent stroke (31, 32), it seems likely that both a very high arterial pressure and a deficiency of cerebral autoregulation are required for development of stroke. Therefore, stroke might not be expected to occur in the WKYU model.

In conclusion, cerebral arteries from uremic hypertensive animals display impaired myogenic constriction but similar response to flow compared with normotensive controls. Spontaneously hypertensive animals manifest similar myogenic tone yet enhanced constriction to flow compared with normotensive controls. The findings might help explain previous observations of impaired cerebral blood flow autoregulation in uremic hypertension and enhanced autoregulatory vasoconstriction in nonuremic hypertension. These data suggest a possible basis for the association of stroke with uremia in humans.

Effect of uremia on cerebral myogenic constriction has previously been studied in nephrectomized SHR and in stroke-prone SHR (25), which develops spontaneous hypertensive glomerulosclerosis as well as stroke. Vessels from these two strains of SHR with renal failure were found to have decreased myogenic tone, determined by their contractile response to a single brief large pressure step. However, such pressure increments, in addition to stimulating myogenic contraction, may elicit transient nitric oxide release from rat cerebral artery endothelium (6) and might therefore underestimate myogenic constriction. Further evaluation of stroke-prone SHR cerebral arteries suggested that levels of myogenic tone were normal (12), although the level of uremia, if present, was not reported. Our study is, therefore, the first to establish the degree of cerebral myogenic constriction in uremia, measured under steady-state conditions, in a normotensive rat strain possessing genetically typical arterioles. The finding of substantially decreased tone in WKYU compared with WKYC and SHR supports the notion of uremic impairment of myogenic constriction. This might explain the impaired cerebral autoregulation seen in uremia in vivo.

Flow-dependent constriction is known to occur in the rat middle cerebral artery; a previous report (2) established that vessels responded with ~15% decrease in diameter when exposed to 100 dyn/cm² shear stress. This value is very similar to that seen in our WKY and likewise appears to be endothelium independent.
