Submitted 30 July 2008; accepted in final form 9 March 2009

Doxorubicin (DOX; Adriamycin), an anthracycline antibiotic, continues to be a widely used chemotherapeutic agent to treat a variety of cancers (55) despite its potential to elicit serious dose-dependent cardiotoxicity often leading to degenerative cardiomyopathy/heart failure (55). The therapeutic options for DOX-induced cardiomyopathy are very limited, mostly involving supportive treatment or cardiac transplantation. The proposed mechanism of DOX-induced cardiotoxicity is complex and involves increased oxidative/nitrosative stress and downstream effector pathways (2, 3, 11, 28, 43–45, 60, 65). Apoptotic cell death is a key component in DOX-induced cardiotoxicity (7, 20, 23, 31, 62); however, the exact triggers/mechanisms have not been fully established, and optimal therapeutic approaches for cardioprotection remain undefined (56).

Peroxynitrite is a reactive oxidant that is produced from the diffusion-controlled reaction between nitric oxide (NO) and another free radical, the superoxide anion (41). In addition to its diffusion-controlled reactions, NO under certain conditions may also react with glutathione to generate S-nitrosoglutathione to be stored in this complexed form (15). In vivo peroxynitrite generation and/or protein nitration have recently been demonstrated in various rodent models of myocardial ischemia-reperfusion and heart failure and in humans with these pathologies (14, 41, 49, 59). Previous studies (28, 43, 65) have also demonstrated increased nitrotyrosine (NT; a footprint of peroxynitrite generation) formation in the myocardium of DOX-treated rodents and hypothesized that the peroxynitrite-induced increased nitration of key myocardial proteins may contribute to the DOX-induced depressed cardiac function. However, these studies only partially addressed the potential sources of superoxide and NO leading to peroxynitrite generation and have not addressed the possible interplays of these free radicals, activities of antioxidant enzymes, and their roles in DOX-induced cell death (both apoptotic and necrotic), which is a major determining factor of its cardiotoxicity.

The goal of the present study was to investigate the role and sources of superoxide, NO, and peroxynitrite in DOX-induced cell death both in vivo and in vitro. To achieve this goal, we used pharmacological tools, inducible NO synthase (iNOS) knockout mice, flow cytometry, fluorescent and confocal microscopy, biochemistry, and molecular biology techniques. We

also used a novel flow cytometric method (32) allowing the simultaneous quantitative detection of mitochondrial superoxide generation with apoptosis markers in live cells to gain insight into the role of mitochondrial superoxide generation in DOX-induced cell death. Herein, by using these multiple tools, we provide unequivocal evidence that peroxynitrite is the major trigger of DOX-induced cell death in cardiomyocytes both in vivo and in vitro.

Fig. 1. Effects of doxorubicin (DOX) with or without peroxynitrite scavengers (PSs) on myocardial inducible nitric oxide (iNOS) expression in vivo.

A: DOX-induced increased myocardial iNOS mRNA (left) and protein (right) levels, which were not affected by PSs. *P < 0.05 vs. vehicle; **P < 0.05 vs. DOX. n = 6 per group for protein samples and n = 9 per group for mRNA samples. B: Immunohistochemistry demonstrated widespread DOX-induced increased myocardial iNOS expression. FeTMPyP, iron α,β,γ,δ-tetakis(4-N-methylpyridyl)porphine; MnTMPyP, manganese α,β,γ,δ-tetakis(4-N-methylpyridyl)porphine.

iNOS, inducible nitric oxide synthase (NOS); eNOS, endothelial NOS; nNOS, neuronal NOS; NOX, NAD(P)H oxidase; MMP, matrix metalloproteinase.
MATERIALS AND METHODS

Animals. All protocols were approved by the Institutional Animal Care and Use Committee and were performed in accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals. Male C57BL/6J, iNOS+/−/− and iNOS−/− mice weighing ~30 g were administered a single dose of DOX HCl (Sigma, St. Louis, MO) at 20 mg/kg ip and used for functional and biochemistry measurements 5 days later, when severe cardiac dysfunction was well established (10, 31, 43, 45, 65). This time point was chosen because it represents >5 final half-lives of elimination of DOX from both plasma and cardiac tissue in mice (63). Treatment with the peroxynitrite decomposition catalyst iron α,β,γ,δ-tetrakis(4-N-methylpyridyl)porphine (FeTMPyP; 10 mg/kg ip) or the peroxynitrite decomposition catalyst/SOD mimetic manganese α,β,γ,δ-tetrakis(4-N-methylpyridyl)porphine (MnTMPyP; 10 mg/kg ip) [also termed peroxynitrite “scavengers” (PSs)] started 1.5 h before the DOX injection and was continued (10 mg·kg⁻¹·day⁻¹ in drinking water) until the hemodynamic measurements were made and animals were killed for the isolation of hearts. In a separate set of experiments, mice were killed 6 h, 1 day, 2 days, 3 days, and 5 days after DOX administration with or without FeTMPyP/MnTMPyP (same doses as mentioned above).

Reagents and cell culture. DOX, sodium nitroprusside (SNP), hydrogen peroxide, SOD-polyethylene glycol (PEG), catalase-PEG, diphenylene iodonium (DPI), allopurinol, and apocynin were purchased from Sigma; IC-I, diethylenetriamine DETANONate, peroxynitrite, peroxynitrite decomposition catalysts (FeTMPyP and MnTMPyP), nitrotyrosine monoclonal antibody, and NT affinity sorbent were from Cayman (Ann Arbor, Michigan); and iNOS inhibitors {S,S'-[1,3-phenylene-bis(1,2-ethanediyl)]bis-isothiourea (1,3-PB-ITU) and L-N6-(1-iminorthyl)-lysine (L-NIL)} were from AXXORA (San Diego, CA). Antibodies were as follows: actin monoclonal antibody and polyclonal NT antibody were from Chemicon (Temecula, CA); cleaved caspase-3 and cytochrome c were from Cell Signaling (Danvers, MA); iNOS was from BD Pharmingen (San Diego, CA); endothelial NOS (eNOS) and neuronal NOS (nNOS) were from Santa Cruz Biotechnology (Santa Cruz, CA); and xanthine oxidase was from Abcam (Cambridge, MA). The microscopy and flow cytometry reagents tetramethylrhodamine ethyl ester (TMRE), Mitotracker green, MitoSOX red, 4-amino-5-methylamino-2',7'-dihydroethidium (DHE), Hoechst 33342, rhodamine 11 bis(L-aspartic acid amide), Sytox green, and annexinV-APC were from Molecular Probes (Invitrogen, Carlsbad, CA).

Fig. 2. Effects of DOX with or without PSs on myocardial superoxide/ROS formation, its sources, and antioxidant enzyme activities in vivo. A: effects of PSs on DOX-induced superoxide/ROS formation from frozen heart sections using dihydroethidium (DHE). *P < 0.05 vs. vehicle; #P < 0.05 vs. DOX. n = 6 per group. B: effects of PSs on DOX-induced myocardial xanthine oxidase mRNA (left) and protein (right) expression. A representative blot from 3 sets of experiments is shown. The blot was also probed for β-actin as a loading control. *P < 0.05 vs. vehicle; #P < 0.05 vs. DOX. n = 6 per group. C: effects of DOX with or without PSs on mitochondrial superoxide/ROS generation in isolated mitochondria. *P < 0.05 vs. vehicle; #P < 0.05 vs. DOX. n = 6 per group. D: effects of DOX with or without PSs on myocardial SOD activity. n = 6 per group. E and F: effects of DOX with or without PSs on myocardial catalase (E) and glutathione peroxidase (F) activities. *P < 0.05 vs. vehicle; #P < 0.05 vs. DOX. n = 6 per group.
Hemodynamic measurements using the pressure-volume conductance system in mice. Left ventricular (LV) performance was analyzed in mice anesthetized with 2% isoflurane. Animals were placed on controlled heating pads, and their core temperature was measured via a rectal probe and maintained at 37°C. The trachea was cannulated, and animals were artificially ventilated using MiniVent respirator (Harvard Apparatus, Holliston, MA) at rates and tidal volumes adjusted to body weights. A 1-Fr microtip pressure-volume (P-V) catheter (PVR 1045, Millar Instruments, Houston, TX) was inserted into the right carotid artery and advanced into the LV as previously described (5, 31, 45, 46). After stabilization for 20 min, signals were continuously recorded at a sampling rate of 1,000 s⁻¹ using an ARIA P-V conductance system (Millar Instruments) coupled to a Powerlab/4SP analog-to-digital converter (AD Instruments, Mountain View, CA), stored, and displayed on a computer. All P-V loop data were analyzed using a cardiac P-V analysis program (PVAN3.6, Millar Instruments), and maximal LV systolic pressure (LVSP), maximal slope of the systolic pressure increment (∆P/∆t), ejection fraction (EF), cardiac output (CO), and stroke work (SW) were computed. All hemodynamic parameters were calculated and corrected according to in vitro and in vivo volume calibrations (5, 31, 45, 46). These parameters were also determined under conditions of changing preload, which was elicited by transiently compressing the inferior vena cava in ventilated anesthetized animals after the thoracotomy. Since ∆P/∆t may be preload dependent (17), in these animals, P-V loops recorded at different preloads were used to derive other useful systolic function indexes that may be less influenced by loading conditions and cardiac mass. These measures include the ∆P/∆t-end-diastolic volume (EDV) relation (17), preload-recruitable SW (PRSW; which represents the slope of the relation between SW and EDV and is independent of chamber size and mass) (17), the end-systolic P-V relation, and maximal elastance (Emax) (35). After the hemodynamic measurements had been completed, animals were euthanized and tissue samples were collected.

Real-time PCR analyses. Total RNA was isolated from tissue (heart) homogenates or from H9c2 cells using TRlzol LS reagents (Invitrogen) according to the manufacturer’s instructions. Isolated RNA was treated with RNase-free DNase (Ambion, Austin, TX) to remove traces of genomic DNA contamination. Total RNA (1 μg) was reverse transcribed to cDNA using Super-Script II (Invitrogen). The target gene expression was quantified with gene-specific primers and iTaq Syber Green Mix (Bio-Rad, Hercules, CA) using the Bio-Rad Chromo 4/Opticon system. Each amplified sample was analyzed for homogeneity using melting curve analysis. Relative quantification was performed using the comparative threshold cycle method. The primers used are shown in Table 1.

Immunoprecipitation for NT detection. Equal amounts of either 200 μg tissue homogenate or 400 μg cell lysate from each sample were incubated with 20 μg of NT affinity sorbent (NT antibody cross-linked to a protein A-agarose matrix) overnight at 4°C in a rotating wheel. The NT affinity sorbent is designed for immunoprecipitation of nitrated proteins from biological samples. Immunoprecipitates were washed five times with PBS containing 0.1% Triton X-100. Pellets were suspended in 1/3 Laemmli buffer with DTT. SDS-PAGE anal...

Fig. 3. Effects of DOX with or without PSs on myocardial nitrotyrosine (NT) formation, matrix metalloproteinase (MMP)-2 and MMP-9 gene expression, and poly(ADP-ribose) polymerase (PARP) and myeloperoxidase (MPO) activities in vivo. A: effects of PSs on DOX-induced NT formation from heart tissue homogenates. B: effects of PSs on DOX-induced myocardial MMP-2 and MMP-9 mRNA expression. *P < 0.05 vs. vehicle; #P < 0.05 vs. DOX. n = 9 per group. C: effects of PSs on DOX-induced myocardial PARP activity. *P < 0.05 vs. vehicle; #P < 0.05 vs. DOX. n = 6 per group. D: effects of DOX with or without PSs on myocardial MPO staining. A representative sample from liver ischemia-reperfusion (I/R) injury with marked neutrophil infiltration as previously described (4, 52) and stained under the same conditions was used as a positive control.
analysis and immunoblots were performed as described below followed by silver staining of protein gels. Silver staining (detection limit: 1 ng protein) was carried out as previously described (13, 14).

**Immunoblot analyses.** Protein was extracted from tissue homogenates using RIPA lysis buffer containing protease inhibitor cocktail set III and phosphatase inhibitor cocktail set I (Calbiochem, EMD Biosciences, San Diego, CA). Equal amounts (40 μg/lane) were fractionated on NuPAGE 4–12% bis-Tris gel and transferred onto nitrocellulose membranes (Invitrogen) using a semidyrd transfer apparatus (Bio-Rad). Blocking was carried out for 2 h in 5% nonfat dry milk in PBS. Primary antibodies were added as per the manufacturer’s recommended dilution in blocking buffer containing 0.1% Tween 20, secondary horseradish peroxidase conjugate (Pierce Biotechnology, Rockford, IL) was added followed by three washes with PBS containing 0.1% Tween 20. Blots were detected with Supersignal West Pico chemiluminescent substrate (Pierce Biotechnology) and developed using Kodak Biomax film (Perkin-Elmer, Wellesley, MA). All blots were normalized to the loading control (β-actin).

**Mitochondrial membrane potential measurements by confocal microscopy.** For the determination of mitochondrial membrane potential, cells were loaded with 50 nM of the fluorescent potential-dependent indicator TMRE for 30 min at 37°C. In an additional set of experiments, we also used ready-to-use JC-1 dye (as recommended by the supplier) for loading cells with 50 nM of the fluorescent potential-dependent indicator TMRE for 30 min at 37°C. After three washes in PBS containing 0.1% Tween 20, secondary horseradish peroxidase conjugate (Pierce Biotechnology) and developed using Kodak Biomax film (Perkin-Elmer, Wellesley, MA). All blots were normalized to the loading control (β-actin).

**Flow cytometry.** Early apoptosis and cytotoxicity were determined by flow cytometry using propidium iodide or Sytox green and annexin V staining (Molecular Probes) according to the manufacturer’s recommendations. Flow cytometry analyses included 5,000 or 10,000 events using a FACScalibur (Becton Dickinson). For the quantitative determination of mitochondrial membrane potential, cells were loaded with 50 nM of the fluorescent potential-dependent indicator TMRE for 30 min at 37°C and collected after trypsinization. The fluorescence intensity was monitored at the FL-2 channel by FACScalibur, and 5,000 events were collected per sample. A mixture of the mitochondrial uncouplers FCCP (5 μM) and oligomycin A (10 μg/ml) was added to disrupt mitochondrial membrane potential as a negative control in flow cytometry experiments as previously described (42) for confocal microscopy. For the determination of mitochondrial superoxide by flow cytometry, cells were incubated with MitoSOX red as previously described (32, 33). All data were acquired and analyzed using Cell quest or Flow Jo (version 8.5) software.

**Mitochondrial superoxide measurement from isolated myocardial mitochondria.** Mitochondria were isolated from the myocardium of mice treated with vehicle, DOX, or DOX + FeTMPyP/MnTMPyP using a tissue mitochondrial isolation kit (Pierce Biotechnology). Isolated mitochondria were allowed to load for 30 min with 5 μM MitoSOX red, and measurements were taken at the FL-2 channel using FACScalibur. Fragmented mitochondria (mitochondrial debris) with low forward and side scatter were excluded from analyses. Mitochondrial debris was generated due to the procedure/method used and was not statistically significant in the different groups (vehicle: 25.6 ± 12.5, DOX: 27.8 ± 11.3, DOX + FeTMPyP: 29.2 ± 9.7, and DOX + FeTMPyP: 22.2 ± 17.2, n = 4 for each group).

**Fluorescence microscopy for caspase activation.** Cells were grown in sterile glass-bottom dishes (MatTek), washed with PBS, stained with the DNA-binding dyes Hoechst 33342 and rhodamine 110 as well as bis-l-aspartic acid amide (final concentration: 1 μM) for 15 min, washed three times with PBS, and then observed under a Olympus IX81 at ×150 magnification for all samples using fluorescence microscopy (31).
Confocal microscopy of frozen heart sections for the determination of superoxide production. Hearts were snap frozen in Tissue-Tek embedding medium (Sakura, Torrance, CA), and sections were made at 10 μm using microtome at −25°C. Sections were air dried and hydrated with PBS. Sections were then incubated with 5 μM DHE at 37°C for 30 min as previously described (21). Detection of NT using confocal microscopy. Cells were processed similarly to the procedure described under Fluorescence microscopy.

Fig. 5. Effects of DOX on myocardial NT generation and caspase-3/7 activity in iNOS knockout mice. A and B: decreased DOX-induced NT formation (A) and apoptosis (B) as measured by myocardial caspase-3/7 activity in iNOS−/− mice compared with wild-type (WT) mice. *P < 0.05 vs. vehicle; #P < 0.05 vs. DOX. n = 9 per group.

Fig. 6. Effects of DOX with or without PSs on myocardial function in vivo. A: effect of PSs on the DOX-induced depression of left ventricular systolic pressure (LVSP), maximal slope of the systolic pressure increment (+dP/dt), ejection fraction, stroke work (SW), and cardiac output in mice. B: effects of PSs on the DOX-induced depression of load-independent indexes of cardiac contractility [dP/dt-end-diastolic volume (EDV) relation, preload-recruitable SW (PRSW), and maximal elastance (Emax)]. Hemodynamic parameters were measured 5 days after DOX administration. Results are means ± SE of 6–12 experiments in each group. *P < 0.05 vs. vehicle; #P < 0.05 vs. DOX.
for caspase activation and stained with NT antibody after being fixed in 4% paraformaldehyde-PBS for 15 min, washed twice in PBS, and permeabilized for 5 min in 0.1% Triton X-100-PBS. Secondary anti-rabbit/mouse FITC or Texas red conjugates were used. For mitochondrial staining, cells were loaded with TMRE and Mitotracker green for 30 min followed by three washes with PBS buffer containing 1% BSA according to the manufacturer’s recommendations. Digital images were taken by a LSM Pascal confocal microscope (Carl Zeiss) at a resolution of 2,048 × 2,048 pixels. Images were captured using either ×40 or ×60 objectives and the optical section was <1 μm.

Determination of NT by ELISA and flow cytometry. NT was measured by the NT ELISA kit from Hycult Biotechnology (Cell Sciences, Canton, MA), and values are presented as fold changes compared with vehicle. Intracellular NT was also determined in H9c2 cardiomyocytes using flow cytometry. After treatment, cells were fixed and permeabilized. After being blocked, cells were incubated with NT monoclonal antibody at 4°C overnight and secondary anti-mouse FITC conjugate for an additional 4 h (27).

Myocardial caspase-3 and caspase-3/7 activity. Caspase-3 activities in tissue extracts were determined using a commercially available kit (Chemicon). In brief, the assay is based on measuring the amount of the chromophore p-nitroaniline (pNA) liberated from the labeled substrate DEVD-pNA at 405 nM. Caspase-3 activities are expressed as fold increases over control (31). Caspase-3/7 activities were also measured using the Apo-one Homogeneous Caspase-3/7 assay kit (Promega) according to the manufacturer’s instructions.

Myocardial catalase assay. Myocardial catalase activity was measured according to the manufacturer’s recommendations (Cayman). Briefly, the catalase assay kit uses the peroxidatic function of catalase for the determination of enzyme activity. The method is based on the reaction of the enzyme with methanol in the presence of an optimal concentration of hydrogen peroxide. The formaldehyde produced is measured spectrophotometrically with 4-amino-3-hydrazino-5-mercapto-1,2,4-triazole (Purpald) as the chromogen. Purpald specifically forms a bicyclic heterocycle with aldehydes, which, upon oxidation, changes from colorless to a purple color (61).

Fig. 7. Effects of DOX with or without PSs and/or iNOS inhibitors on mitochondrial superoxide generation and cell death in H9c2 cardiomyocytes in vitro. A: effects of DOX with or without PSs on cell death and mitochondrial superoxide generation in vitro as measured by quantitative flow cytometry. *P < 0.05 vs. vehicle; #P < 0.05 vs. DOX. n = 6 per group. B: effects of iNOS inhibitors [5,5'-[1,3-phenylene-bis(1,2-ethanediyl)]bis-isothiourea (1,3-PB-ITU) and L-Ν6-(1-iminoethyl)-lysine (L-NIL)] on DOX-induced cell death in vitro. *P < 0.05 vs. vehicle; #P < 0.05 vs. DOX. n = 9 per group.
**Myocardial SOD assays.** Myocardial SOD activity was measured according to the manufacturer’s instructions (Trevigen, Gaithersburg, MD). In this colorimetry-based assay, superoxide ions are generated from the conversion of xanthine and oxygen to uric acid and hydrogen peroxide by xanthine oxidase. The superoxide anion then converts WST-1 to WST-1 formazan, a colored product that absorbs light at 450 nm. SOD reduces the superoxide ion concentration and thereby lowers the rate of WST-1-formazan formation. A reduction in the appearance of WST-1-formazan is a measure of SOD activity present in the experimental sample (18).

**Myocardial glutathione peroxidase assay.** Glutathione peroxide enzyme activity were assayed using a SpectraMax spectrophotometer according to the manufacturer’s instructions (Trevigen). One unit of glutathione peroxidase is defined as the amount of the enzyme that will cause the oxidation of 1 nmol of NADPH to NADP⁺ per minute at 25°C (40).

**Myocardial PARP activity.** PARP activity was assayed by colorimetry according to the manufacturer’s instructions (Trevigen). The PARP Universal Colorimetric Assay Kit measures the incorporation of biotinylated poly(ADP-ribose) onto histone proteins in a 96-well plate and has sensitivity down to 0.01 units of PARP per well (1).

**Immunohistological analysis of heart tissue.** Heart tissue was fixed in 4% buffered formalin. After tissue had been embedded and cut into 5-μm slices, all sections were stained with hematoxylin and eosin. Myeloperoxidase (MPO) staining of neutrophils was done using

---

**Fig. 8. Effects of PSs on DOX-induced mitochondrial dysfunction in vitro.**

**A:** effects of PSs (200 μM) on DOX-induced dissipation of mitochondrial membrane potential (as measured by TMRE) in H9c2 cells using flow cytometry. Various controls are also shown at the far right, including vehicle without TMRE, vehicle with TMRE, and dissipation of mitochondrial potential by FCCP + oligomycin A (Oligo A) for 2 and 30 min after exposure. **B:** effects of PSs (200 μM) on DOX-induced dissipation of mitochondrial membrane potential measured in H9c2 cells loaded with JC-1 using confocal microscopy. Magnification: x600.
anti-MPO antibody (1:100 dilution, DAKO, Carpinteria, CA) (4, 52) according to the manufacturer’s protocol, and samples were counterstained with hematoxylin. In other staining procedures, NT (1:100 dilution, Cayman) and iNOS (1:100 dilution, BD Bioscience) were stained according to the manufacturer’s instructions and counterstained with nuclear fast red and hematoxylin, respectively. Histological evaluation was performed in a blinded manner.

Statistical analysis. Results are reported as means ± SE. Statistical significance among groups was determined by one-way ANOVA followed by post hoc Newman-Keuls analysis using GraphPad Prism 4.3 software. Statistical analyses between two measurements were determined by the two-tailed unpaired Student’s t-test. Correlations were determined by GraphPad Prism 4.3 software.

RESULTS

DOX induces increased myocardial iNOS, but not eNOS and nNOS, expression and enhanced myocardial NT generation: effects of PSs. DOX induced ~4- and ~2.5-fold increases in myocardial iNOS (but not eNOS and nNOS) protein and mRNA expression (Fig. 1A and Supplemental Fig. 3) at 5 days after exposure, which was not affected by PSs. DOX also increased iNOS expression in cardiomyocytes as measured by immunostaining (Fig. 1B) at day 5. DOX-induced significant increases in myocardial iNOS protein expression and NT generation and increases in caspase-3/7 activities were evident 1 day after exposure to the drug and peaked at around days 4–5 (Supplemental Fig. 1). PSs had no significant effects on iNOS protein expression; however, they attenuated the course of DOX-induced NT formation and decreased DOX-induced myocardial apoptosis.

DOX increases myocardial ROS generation: effects of PSs. DOX induced an approximately sixfold increase in superoxide/ROS generation as measured by DHE fluorescence using confocal microscopy from frozen sections, which was not significantly decreased by PSs (Fig. 2A). There were no statistically significant increases in the gene expression (expressed as fold changes compared with vehicle) of NAD(P)H oxidase isoform 1 (NOX1; 1.0 ± 0.17, 0.92 ± 0.18, 0.73 ± 0.14, and 0.91 ± 0.19), NAD(P)H oxidase isoform 2 (NOX2; 1.0 ± 0.09, 1.18 ± 0.23, 1.21 ± 0.26, and 1.1 ± 0.27), p22phox (1.0 ± 0.09, 0.78 ± 0.12, 0.91 ± 0.16, and 0.83 ± 0.18), p47phox (1.0 ± 0.19, 0.79 ± 0.14, 0.84 ± 0.21, and 0.81 ± 0.18), p47phox (1.0 ± 0.12, 1.1 ± 0.18, 0.92 ± 0.19, and 1.05 ± 0.17), and p67phox (1.0 ± 0.15, 1.31 ± 0.19, 1.26 ± 0.13, and 1.15 ± 0.27) in the vehicle-, DOX-, DOX + FeTMPyP-, and DOX + MnTMPyP-treated groups, respectively (n = 6 per group). Xanthine oxidase mRNA but not...
protein levels were increased to \( \sim 1.8 \pm 0.2 \)-fold by DOX (Fig. 2B).

DOX treatment of mice markedly increased mitochondrial superoxide generation as measured from isolated cardiac mitochondria loaded with MitoSOX, which was not significantly attenuated by PSs (Fig. 2C).

To evaluate the possible role of SOD, catalase and glutathione peroxidase activities were measured (Fig. 2, D–F). SOD activity was not significantly different among all groups studied (Fig. 2D), but DOX decreased catalase and glutathione peroxidase activities, and these decreases were attenuated by PSs (Fig. 2, E and F).

**DOX increases myocardial NT formation, matrix metalloproteinase-2/9 gene expression, and PARP activity, which are attenuated by PSs.** DOX induced a marked increase of myocardial NT formation (as measured using immunoprecipitation of NT-modified protein) 5 days after DOX administration to mice, which was largely prevented by PSs (Fig. 3A; see also Supplemental Fig. 1 for ELISA data). Since matrix metalloproteinases (MMPs) and PARP are well-known downstream effectors of peroxynitrite/ROS-induced myocardial injury (41, 54), we also measured MMP-2 and MMP-9 gene expression and PARP activity from the myocardium of mice, which are known to be increased by DOX (3). DOX increased myocardial MMP-2 and MMP-9 mRNA expression and PARP activity by approximately two- to threefold, which were attenuated by FeTMPyP/MnTMPyP (Fig. 3, B and C).

**DOX triggers myocardial apoptosis, which is markedly attenuated by PSs.** DOX treatment markedly increased (by 3- to 5-fold) cytochrome c release into the cytoplasm, myocardial caspase-3 cleavage, caspase-3 activity, caspase-3 and -9 gene expression, and DNA fragmentation as measured by quantitative TUNEL assay, which were markedly attenuated by PSs (Fig. 4, A–E).

**Attenuated DOX-induced myocardial NT formation and cell death in iNOS knockout mice compared with their wild-type littermates.** DOX induced a marked increase of myocardial NT formation and caspase-3/7 activity in wild-type mice, whereas these effects were significantly attenuated in iNOS knockout mice (Fig. 5, A and B).

**DOX-induced cardiac dysfunction is attenuated by PSs.** DOX-induced cardiac dysfunction fully developed after 3 days after the administration of the drug (Supplemental Fig. 2), consistently with other reports (31, 43–45, 53, 65), and was similar to that previously described in more chronic models of this cardiomyopathy (10, 43). PSs markedly improved the DOX-induced decline in various load-dependent indexes (+dp/dt, LVSP, EF, SW, and CO) and load-independent indexes (dP/dt-EDV, PRSW, and \( E_{\max} \)) of myocardial contractility (Fig. 6, A and B).

**Fig. 10.** Effects of PSs on peroxynitrite-induced apoptosis/necrosis and NT generation in vitro. A: effects of PSs (200 \( \mu \)M) on peroxynitrite-induced apoptosis/necrosis as measured by flow cytometry in H9c2 cardiomyocytes. The treatment of peroxynitrite was described previously (Ref. 22). Representative data from 4 experiments were analyzed. \( *P < 0.05 \) vs. vehicle; \( \#P < 0.05 \) vs. DOX. \( n = 4 \) per group. B: effects of DOX and peroxynitrite on NT formation in H9c2 cells as measured by quantitative ELISA. \( *P < 0.05 \) vs. vehicle; \( n = 4 \) per group. C: effects of PSs on peroxynitrite-induced NT formation (green). Representative data from 8 experiments are shown. Magnification: \( \times 600 \).
Effects of PSs on DOX-induced increased mitochondrial superoxide formation in vitro. Treatment of H9c2 cells with DOX at 1 μM for 16 h induced an ~5.7-fold increase in mitochondrial superoxide production. Treatment of cells with MnTMPyP, but not FeTMPyP, attenuated the DOX-induced mitochondrial superoxide generation (Fig. 7A).

Effects of selective iNOS inhibitors on DOX-induced cell death. The selective iNOS inhibitors 1,3-PB-ITU and l-NIL significantly attenuated DOX-induced cell death (Fig. 7B).

Effect of PSs on DOX-induced mitochondrial dysfunction, cell death, and peroxynitrite-dependent NT formation in vitro. DOX dose dependently decreased mitochondrial membrane potential [as measured by confocal microscopy (Supplemental Fig. 4) or flow cytometry (Fig. 8A) using TMRE or by confocal microscopy using JC-1 (Fig. 8B)] and increased apoptosis in H9c2 cardiomyocytes (Figs. 9, A–C); these effects were largely preventable by PSs. PSs also prevented DOX- or peroxynitrite-induced increased NT formation and cell death in vitro (Figs. 9 and 10). DOX-induced NT formation was localized in the mitochondria, as shown by the yellow color in Fig. 11 (middle left overlay image), and was also present in the cytosol, as shown by the red color in Fig. 11 (middle left overlay image).

NO donors enhance DOX-induced cell death and NT formation without major effects without DOX. NO donors [DETA-NONOate (Figs. 12 and 13A) and SNP and SIN-1 (Supplemental Fig. 7)] enhanced DOX-induced cell death and NT formation (Fig. 13 and Supplemental Fig. 8) without major effects without DOX. DOX-induced increased NT formation positively correlated with apoptotic/necrotic cell death in H9c2 cells (Fig. 13).

DETA NONOate attenuates DOX-induced superoxide generation with concomitant increased cell death and increased intracellular NT generation. The NO donor DETA NONOate attenuated the DOX-induced superoxide generation (Fig. 14) with concomitant increased cell death and increased intracellular NT generation (see above and Figs. 12 and 13 and Supplemental Fig. 7).

DOX-induced cell death is attenuated by SOD-PEG but not by allopurinol, apocynin, DPI, or catalase-PEG. DOX-induced cell death was attenuated by cell-permeable SOD-PEG but not the xanthine oxidase inhibitor allopurinol, the NADPH oxidase inhibitors apocynin and DPI, or cell-permeable catalase-PEG (Supplemental Figs. 5 and 6). In contrast, catalase-PEG attenuated hydrogen peroxide-induced dose-dependent cell death (Supplemental Fig. 6), indicating that hydrogen peroxide is not the main mediator of DOX-induced cell death in vitro. Consistently with several recent reports (e.g., Ref. 26), DPI by itself induced marked cell death (Supplemental Fig. 5), suggesting a serious note of caution in using this compound as a NADPH oxidase inhibitor for in vitro studies.

![Fig. 11. Effects of DOX with or without PSs on intracellular NT formation. Shown are the effects of PSs on the intracellular localization of DOX-induced NT formation (red) and the mitochondrial dye Mitotracker green by confocal microscopy. Magnification: ×800.](http://ajpheart.physiology.org/lookup/doi/10.220.33.2)
Because of its superior efficacy and broad-spectrum action, DOX continues to be a commonly used chemotherapeutic agent despite its cardiotoxicity (55). Preclinical and clinical studies have suggested that increased oxidative/nitrosative stress associated with an impaired antioxidant defense status plays a critical role in DOX-induced subcellular remodeling, Ca\textsuperscript{2+}/\textit{H}\textsubscript{1001}\textsuperscript{2+}-handling abnormalities, and alteration of cardiac energetics, eventually culminating into cellular dysfunction and death, with subsequent cardiomyopathy and heart failure (3, 11, 28, 43–45, 56, 57, 60, 65).

Our results indicated that the mitochondrion is a pivotal source of superoxide generation after DOX exposure both in vivo and in vitro, and peroxynitrite formed in cardiomyocytes and most likely endothelial cells through diffusion-limited reaction of iNOS-derived NO and superoxide is a major trigger/mediator of DOX-induced apoptotic cell death, which is a key component of DOX-induced cardiotoxicity. Treatment with two PSs prevented the DOX-induced marked increase in myocardial apoptotic cell death as measured by multiple markers, contractile dysfunction, and myocardial NT formation in a well-established mouse model of DOX-induced acute heart failure in vivo. The time point of 5 days after a single dose of DOX for functional and other assessments was chosen because by this time, DOX is eliminated and no longer present in the blood or cardiac tissues (63).

NT formation was initially considered as a specific marker of in vivo peroxynitrite generation, but now it is rather used as a collective index of reactive nitrogen species, because other pathways inducing tyrosine nitration have also been proposed [e.g., MPO in certain inflammatory conditions (41)]. However, our experiments demonstrated that MPO cannot contribute to NT generation in this model, since normal and DOX-treated mouse hearts were MPO negative (Fig. 3D); thus, the increased NT most likely originates from increased endogenous peroxynitrite formation in our model. This was also supported by decreased NT formation in iNOS knockout mice treated with DOX (Fig. 5). We observed a time-dependent increase in myocardial NT formation after DOX exposure (Supplemental Fig. 1), which peaked at day 5, when the myocardial dysfunction was fully developed in our in vivo model (31, 43–45, 65) (Supplemental Fig. 2). This is also consistent with the highly significant inverse relationship between LV fractional shortening and cardiac NT immunoprevalence observed in a previous study (65).

Using flow cytometry, fluorescent and confocal microscopy, biochemistry, and molecular biology techniques, we also demonstrated that DOX, similarly to exogenously applied peroxynitrite (22), induces marked dose-dependent increases in cellular NT formation, dissipation of mitochondrial membrane potential, cytochrome c release, and execution of the mitochon-

**DISCUSSION**

Because of its superior efficacy and broad-spectrum action, DOX continues to be a commonly used chemotherapeutic agent despite its cardiotoxicity (55). Preclinical and clinical studies have suggested that increased oxidative/nitrosative stress associated with an impaired antioxidant defense status plays a critical role in DOX-induced subcellular remodeling, Ca\textsuperscript{2+}/\textit{H}\textsubscript{1001}\textsuperscript{2+}-handling abnormalities, and alteration of cardiac energetics, eventually culminating into cellular dysfunction and death, with subsequent cardiomyopathy and heart failure (3, 11, 28, 43–45, 56, 57, 60, 65).

Our results indicated that the mitochondrion is a pivotal source of superoxide generation after DOX exposure both in vivo and in vitro, and peroxynitrite formed in cardiomyocytes and most likely endothelial cells through diffusion-limited reaction of iNOS-derived NO and superoxide is a major trigger/mediator of DOX-induced apoptotic cell death, which is a key component of DOX-induced cardiotoxicity. Treatment with two PSs prevented the DOX-induced marked increase in myocardial apoptotic cell death as measured by multiple markers, contractile dysfunction, and myocardial NT formation in a well-established mouse model of DOX-induced acute heart failure in vivo. The time point of 5 days after a single dose of DOX for functional and other assessments was chosen because by this time, DOX is eliminated and no longer present in the blood or cardiac tissues (63). This is very important from the clinical point of view, because the cardiotoxicity of DOX in most patients develops a long time after the initial exposure to the drug.

NT formation was initially considered as a specific marker of in vivo peroxynitrite generation, but now it is rather used as a collective index of reactive nitrogen species, because other pathways inducing tyrosine nitration have also been proposed [e.g., MPO in certain inflammatory conditions (41)]. However, our experiments demonstrated that MPO cannot contribute to NT generation in this model, since normal and DOX-treated mouse hearts were MPO negative (Fig. 3D); thus, the increased NT most likely originates from increased endogenous peroxynitrite formation in our model. This was also supported by decreased NT formation in iNOS knockout mice treated with DOX (Fig. 5). We observed a time-dependent increase in myocardial NT formation after DOX exposure (Supplemental Fig. 1), which peaked at day 5, when the myocardial dysfunction was fully developed in our in vivo model (31, 43–45, 65) (Supplemental Fig. 2). This is also consistent with the highly significant inverse relationship between LV fractional shortening and cardiac NT immunoprevalence observed in a previous study (65).

Using flow cytometry, fluorescent and confocal microscopy, biochemistry, and molecular biology techniques, we also demonstrated that DOX, similarly to exogenously applied peroxynitrite (22), induces marked dose-dependent increases in cellular NT formation, dissipation of mitochondrial membrane potential, cytochrome c release, and execution of the mitochon-
drial phase of caspase-3-dependent apoptosis in H9c2 cardiomyocytes. Likewise, as observed in an in vivo model, these proapoptotic effects of DOX (similar to the effects of exogenously applied peroxynitrite) could be prevented by two different PSs in vitro (Figs. 9 and 10). DOX-induced NT formation was strongly colocalized with mitochondria and was also present throughout the cytosol in cardiomyocytes. Mitochondria are particularly vulnerable targets of peroxynitrite toxicity, and peroxynitrite can lead to alterations of mitochondrial energy and Ca\textsuperscript{2+}/H\textsubscript{1001} homeostasis and promotes the opening of the permeability transition pore, cytochrome c release, and execution of the mitochondrial phase of apoptosis (41, 51). In addition, oxidative/nitrosative stress may also impair various key mitochondrial enzymes of the respiratory chain (these enzymes are particularly sensitive targets of peroxynitrite-induced damage), leading to sustained ROS generation in mitochondria after the initial insult/injury (12, 29, 51). Since peroxynitrite is produced from the diffusion-controlled reaction between NO and superoxide anion, it can easily be formed in large amounts when superoxide and NO are produced simultaneously in close proximity (41, 49, 59).

It has previously been demonstrated using isolated heart mitochondria that DOX forms a complex with cardiolipin within the mitochondrial inner membrane of cardiomyocytes, where it is reduced by NADH dehydrogenase from the respiratory chain to form a semiquinone radical. The semiquinone radical is then oxidized back to the parental compound by passing the electron received onto molecular oxygen, forming a superoxide radical (11, 41). This is consistent with our present observation showing markedly increased superoxide generation in isolated cardiac mitochondria of DOX-treated mice or in mitochondria of live H9C2 myocytes exposed to DOX (32). The pivotal role of mitochondrial superoxide generation in DOX-induced cardiotoxicity is also supported by the lack of major changes in NOX1, NOX2, p22\textsubscript{phox}, p40\textsubscript{phox}, p47\textsubscript{phox}, p67\textsubscript{phox}, and xanthine oxidase expression in hearts of...
DOX-treated mice and the inability of allopurinol, apocynin, and DPI to attenuate DOX-induced cell death in vitro. However, some minor contribution of NAD(P)H and xanthine oxidase to in vivo superoxide generation cannot be ruled out, and a recent study (36) using cardiосpecific eNOS knockout mice has also proposed that under such conditions, eNOS is uncoupled and produces superoxide rather than NO (36).

We found increased iNOS (but not eNOS and nNOS) protein and mRNA expression in the myocardium of DOX-treated mice, suggesting that iNOS is the predominant source of DOX-induced increased NO formation to generate peroxynitrite in the mitochondria and cytosol [NO can easily diffuse through cellular compartments and membranes to form peroxynitrite when superoxide is readily available (41)]. The increase in myocardial iNOS protein expression after DOX exposure peaked around days 4–5, when myocardial dysfunction and NT formation were also evident (Supplemental Fig. 1). In agreement with our results, in the same mouse model of DOX-induced acute heart failure, increased iNOS expression has been previously reported in both acute and chronic rodent models by other groups (2, 24, 38). This is also consistent with the better preservation of cardiac function in DOX-exposed iNOS knockout mice (43) compared with their wild-type littermates and improved cardiac function and decreased DOX-induced histological damage in aminoguanidine-treated mice or rats (8, 30, 43). In contrast to all of these studies, Cole et al. (9), using iNOS knockout mice on different background, suggested that the inhibition of iNOS may be deleterious.

To further investigate the role of NO, iNOS, superoxide, and peroxynitrite in DOX-induced cell death, we studied the effect of two selective iNOS inhibitors (1,3-PB-ITU and L-NIL) on DOX-induced apoptosis in H9c2 cells using quantitative flow cytometry. These experiments revealed that iNOS inhibitors attenuated DOX-induced apoptosis in vitro, consistently with attenuated apoptosis in the myocardium of DOX-treated iNOS knockout mice compared with their wild types. Our results also demonstrated that various NO donors (DETA NONOate, SNP, and SIN-1) dramatically enhanced DOX-induced cell death with concomitant increases in intracellular NT formation while having only a modest effect in the absence of DOX. Importantly, the cellular NT content positively correlated with cell execution. Consistently, the natural phenolic antioxidant oleuropein protects against DOX-induced histological damage in an acute model of rat heart failure by reducing myocardial iNOS expression and NT formation (2). Furthermore, recent studies have also demonstrated that the cardiac-targeted expression of soluble Fas (38) or fluvastatin (53) attenuated DOX-induced cardiotoxicity by decreasing either iNOS expression or NT formation or both.

Collectively, our results suggest that superoxide is not the primary mediator of the mitochondrial phase of DOX-induced apoptosis, since prevention of the DOX-induced increase in NO by iNOS inhibition or by using iNOS knockout mice attenuated cell death but not the increase in mitochondrial superoxide generation induced by DOX. Furthermore, various NO donors when coadministered with DOX but not alone dramatically enhanced DOX-induced cell death and NT generation (Figs. 12 and 13 and Supplemental Fig. 7) with concomitant attenuation of mitochondrial superoxide generation (Fig. 14; because the excess NO reacted with DOX-induced increased superoxide to form peroxynitrite). Furthermore, in vitro, the mitochondrial superoxide generation occurs within minutes after DOX administration to cardiomyocytes or human or murine endothelial cells (32, 33), whereas cell death is evident only ~8–14 h later (present study) when significant amounts of intracellular peroxynitrite is generated, which significantly correlates with cell death (both apoptotic and necrotic; Fig. 13C). DOX-induced increased superoxide/ROS generation is also an early event in vivo, as demonstrated by numerous studies (e.g., Refs. 6, 16, and 43), whereas more significant histological damage, cell death, and cardiac dysfunction peak only later (when DOX is no longer present in the circulation/myocardium), concomitantly with the increased myocardial NT formation (43, 53, 65) (Supplemental Figs. 1 and 2).

NO is not likely to be the trigger of apoptosis either, since NO donors by themselves (without DOX-induced increased superoxide production) have only modest effects on cell death and NT formation, whereas cell death is dramatically enhanced in the presence of DOX. It also appears that hydrogen peroxide is not involved in DOX-induced cell death, at least not in our in vitro system, since cell-permeable catalase was not able to attenuate DOX-induced cell death, whereas it almost completely prevented the cell death induced by various concentrations of hydrogen peroxide (Supplemental Fig. 6).

The most likely trigger of DOX-induced apoptosis/necrosis is peroxynitrite, since PSs effectively prevented not only DOX-

**Fig. 14.** Effects of NO donors on DOX-induced mitochondrial superoxide formation in vitro. Shown are the effects of NO donors in both short-term (4 h; A) and long-term (16 h; B) DOX-induced mitochondrial superoxide formation. *P < 0.001 vs. vehicle; #P < 0.001 vs. the corresponding DOX concentration. n = 6 per group.
induced cell death and contractile dysfunction but also reduce NT formation in cardiomyocytes, which positively correlates with cell death. This is further supported by the findings that PSs also attenuate the activation of known effector pathways for myocardial injury triggered by peroxynitrite (e.g., the activation of the nuclear enzyme PARP-1 and MMPs) in our DOX-induced heart failure model. Pharmacological inhibition of PARP or genetic deletion of PARP-1 is known to be protective in mouse models of DOX-induced cardiomyopathy/heart failure (44, 45), whereas the precise role and consequences of MMP activation (3, 19, 58) deserve additional exploration.

We propose that DOX initially rapidly increases mitochondrial superoxide and other ROS generation in cardiomyocytes and/or endothelial cells by redox cycling [marked DOX-induced superoxide/ROS generation already occurs in exposed cardiomyocytes and endothelial cells within several minutes after exposure (39, 64)], leading to the activation of transcription factor NF-\(\kappa\)B (and perhaps other transcription factors to be explored in the future studies), which is an important early event after DOX exposure both in vitro and in vivo (39, 64). This is followed by increased NF-\(\kappa\)B (or other transcription factor dependent) iNOS expression and consequent NO generation, the mechanisms of which should be evaluated in future studies. A minor contribution of other NOS isoforms to overall DOX-induced increased NO formation, e.g., in endothelial cells, cannot be excluded.

However, irrespective of the source of its generation, excess NO reacts with superoxide to form peroxynitrite both in the cytosol and mitochondria, which, in turn, induces cell damage via lipid peroxidation, inactivation of enzymes and other proteins by oxidation and nitration, and activation of stress signaling pathways (e.g., MAPK), MMPs, and PARP-1, among others. In the mitochondria, peroxynitrite, in concert with other ROS/reactive nitrogen species, impairs various key mitochondrial enzymes, leading to more sustained intracellular ROS generation (persistent even after DOX already metabolized), triggering further activation of transcription factor(s) and iNOS expression, resulting in the amplification of oxidative/nitrosative stress. In the mitochondria, peroxynitrite also triggers the release of proapoptotic factors (e.g., Cyt-C and apoptosis-inducing factor) mediating caspase-dependent and -independent cell death pathways, which are also pivotal in DOX-induced cardiotoxicity. Peroxynitrite, in concert with other oxidants, also causes strand breaks in DNA, activating the nuclear enzyme PARP-1. Once excessive oxidative and nitrosative stress-induced DNA damage occurs, overactivated PARP initiates an energy-consuming cycle by transferring ADP-ribose units from NAD\(^+\) to nuclear proteins, resulting in the rapid depletion of intracellular NAD\(^+\) and ATP pools, slowing the rate of glycolysis and mitochondrial respiration, eventually leading to cellular dysfunction and death, mostly by necrosis. Overactivated PARP may also facilitate the expression of a variety of inflammatory genes leading to increased inflammation (PARP-1 is a known coactivator of NF-\(\kappa\)B) and associated oxidative stress, thus facilitating the progression of cardiovascular dysfunction and heart failure. PARG, poly(ADP-ribose) glycohydrolase.
cytosol and mitochondria, inducing cell damage via lipid peroxidation, inactivation of enzymes and other proteins by oxidation and nitration (e.g., proteins involved in the contractile function and mitochondrial respiration), and also activation of stress signaling pathways (41) [e.g., MAPK (50), which is also involved in DOX-induced cardiotoxicity (25)], MMPs (3, 19, 54, 58), and PARP-1 (41, 47). In the mitochondria, peroxynitrite, in concert with other ROS/reactive nitrogen species, may impair various key mitochondrial enzymes leading to more sustained intracellular ROS generation (persistent even after DOX is already metabolized and no longer present in the circulation/myocardium), triggering the further activation of transcription factor(s) and iNOS expression, resulting in an amplification of oxidative/nitrosative stress. In the mitochondria, peroxynitrite also triggers the release of proapoptotic factors such as cytochrome c and apoptosis-inducing factor, which mediate caspase-dependent and -independent apoptotic death pathways (41), which are also pivotal in DOX-induced cardiotoxicity. Peroxynitrite, in concert with other oxidants, also causes strand breaks in DNA, activating the nuclear enzyme PARP-1. Once excessive oxidative and nitrosative stress-induced DNA damage occurs, overactivated PARP initiates an energy-consuming cycle by transferring ADP-ribose units from NAD\(^+\) to nuclear proteins, resulting in the rapid depletion of intracellular NAD\(^+\) and ATP pools, slowing the rate of glycolysis and mitochondrial respiration, eventually leading to cellular dysfunction and death, mostly by necrosis (41). Overactivated PARP may also facilitate the expression of a variety of inflammatory genes leading to increased inflammation and associated oxidative stress (48, 49), thus facilitating the progression of cardiovascular dysfunction and heart failure (Fig. 15). At a later stage of severe cardiac dysfunction/heart failure, numerous secondary pathways may also be activated [e.g., neuropeptides/neurohormones (angiotensin II, norepinephrine, and endothelin) or proinflammatory cytokines (TNF-\(\alpha\) and IL-6)] acting directly on the myocardium or indirectly via changes in hemodynamic loading conditions to cause additional oxidative/nitrosative stress, endothelial and myocardial dysfunction, cardiac and vascular remodeling with hypertrophy, fibrosis, cardiac dilation, and myocardial necrosis, leading eventually to heart failure (47).

Collectively, our data suggest that endogenous peroxynitrite formation is the major trigger of DOX-induced mitochondrial and PARP-dependent cell death in cardiomyocytes, and the modulation of the pathways leading to its generation or its effective neutralization can be of significant therapeutic benefit (Fig. 15). These results are in line with previous reports (41, 47, 49, 59) suggesting that in vivo peroxynitrite generation and/or protein nitration represents a crucial pathogenic mechanism in various cardiovascular pathophysiology. Our results also suggest that the administration of NO donors should be avoided during the course of acute DOX infusion therapy, because of the increased chance of myocardial peroxynitrite formation and consequent cardiotoxicity.

ACKNOWLEDGMENTS
This report is dedicated to P. Pacher’s mother, Iren Bolfert, who died from cardiovascular complications of chemotherapy.
