Faggioni M, Knollmann BC. Calsequestrin 2 and arrhythmias. Am J Physiol Heart Circ Physiol 302: H1250–H1260, 2012. First published December 23, 2011; doi:10.1152/ajpheart.00779.2011.—Calsequestrin is the most abundant Ca-binding protein of the specialized endoplasmic reticulum found in muscle, the sarcoplasmic reticulum (SR). Calsequestrin binds Ca with high capacity and low affinity and importantly contributes to the mobilization of Ca during each contraction both in skeletal and cardiac muscle. Surprisingly, mutations in the gene encoding the cardiac isoform of calsequestrin (Casq2) have been associated with an inherited form of ventricular arrhythmia triggered by emotional or physical stress termed catecholaminergic polymorphic ventricular tachycardia (CPVT). Despite normal cardiac contractility and normal resting ECG, CPVT patients present with a high risk of sudden death at a young age. Here, we review recent new insights regarding the role of calsequestrin in genetic and acquired arrhythmia disorders. Mouse models of CPVT have shed light on the pathophysiological mechanism underlying CPVT. Casq2 is not only a Ca-storing protein as initially hypothesized, but it has a far more complex function in Ca handling and regulating SR Ca release channels. The functional importance of Casq2 interactions with other SR proteins and the importance of alterations in Casq2 trafficking are also being investigated. Reports of altered Casq2 trafficking in animal models of acquired heart diseases such as heart failure suggest that Casq2 may contribute to arrhythmia risk beyond genetic forms of Casq2 dysfunction.

catecholaminergic polymorphic ventricular tachycardia; cardiac arrhythmia; calcium handling

Introduction

In cardiac muscle, excitation-contraction coupling is regulated by voltage-gated Ca influx through the sarcolemmal L-type Ca channels (8). The resulting increase in the cytosolic Ca concentration triggers the opening of cardiac ryanodine receptor (RyR2) Ca release channels located in the terminal cisternae of the sarcoplasmic reticulum (jSR), the main intracellular Ca-storage compartment (Fig. 1A) (37). Tethered to RyR2 Ca release channel complex (108) are polymers of the cardiac isoform of calsequestrin, calsequestrin 2 (Casq2), which is a low-affinity high-capacity Ca-binding protein thought to provide much of the Ca released from the SR during each heart beat (Fig. 1A) (66).

The released Ca binds to troponin C on the myofilaments starting the contraction. Relaxation occurs when Ca release ceases and the cytosolic Ca concentration returns to diastolic values. Ca is removed from the cytosol by three independent mechanisms: 1) reuptake of Ca into the SR via a Ca-ATPase pump (SERCA); 2) extrusion from the cell via the Na/Ca exchanger (NCX), and to a lesser degree by the sarcolemmal Ca-ATPase pump; and 3) mitochondrial uptake via the Ca uniporter. Together, these mechanisms effectively reduce the cytosolic Ca ions promoting Ca dissociation from the myofilaments (7).

Arrhythmogenic SR Ca release occurs when RyR2 Ca release channels open spontaneously without being triggered by voltage-gated Ca influx. As shown in Fig. 1B, the spontaneous SR Ca release activates the electrogenic NCX and produces a delayed afterdepolarization (DAD; Ref. 36). Premature DAD-triggered action potentials can result in life-threatening ventricular tachycardia and have been implicated as the underlying mechanism responsible for familial arrhythmia disorders caused by mutations in the genes encoding RyR2 or Casq2 (50, 75). This review focuses on Casq2 properties and physiological functions and on the role of Casq2 in the pathophysiology of genetic as well as acquired arrhythmia disorders.

Properties of Casq2 and Its Role in Ca Handling

Protein conformation and characteristics. Calsequestrin is a glycoprotein isolated for the first time in the early 1970s from the SR of rabbit skeletal muscle (63). A few years later the cardiac-specific isoform Casq2 was identified (11). Amino acid sequencing and crystal structure studies have shed light on the conformation of this molecule: Casq2 is composed of three domains each with negatively charged thioredoxin-like folds with four α-helix surrounding a β-sheet core. The center of...
each domain is hydrophobic due to high aromatic acid content, whereas the exterior domain surfaces have an electronegative potential due to a large number of acidic residues. The interdomain space and connecting loops also contain many acidic residues, rendering the core of the molecule overall hydrophilic (100).

Therefore, to stabilize the molecular core, a divalent cation such as Ca is required, inducing at the same time conformational changes that further increase its Ca-binding capability (100). Formation of a Casq2 dimer creates additional negatively charged pockets that can absorb more Ca than two single monomers (100). Initially, the intermolecular binding occurs by front to front dimer formation through the N-terminal arms of Casq2. At higher Ca concentrations, back to back binding occurs through acidic C-terminal tails, producing tetramers. Salt bridges stabilize the union. Deletion of either the N terminal or C terminal of the monomers results in the incapability of the molecule to form linear polymers (5). Polymerization can also be inhibited by K ions that compete with Ca ions in binding to Casq2, but being a monovalent cation, K fails to produce cross bridges with other monomers (4, 70). Ca-induced dimerization starts at ion concentrations in the range of 0.5–1 mM, and at 3 mM Ca there is a detectable tetramer population (69). Once the polymeric state is reached ~40 Ca ions are bound to the molecule (66).

**Cellular localization and function.** Electron microscopy images of muscle fiber thin sections show that Casq2 is localized in the terminal cisternae and is connected to the jSR membrane (24). Casq2 binds to the ryanodine receptor Ca channel (RyR2) in the SR through two proteins, triadin and junctin (Fig. 1), which, extending from the junctional face of the membrane into the lumen of the SR, form a trimeric complex with Casq2 and are involved in the regulation of Ca releases (84). Owing to its high Ca-binding capacity (40–50 mol Ca/mol Casq2) and yet low affinity to Ca (Kd = 1 mM; Refs. 19, 87), Casq2 is not only able to buffer large quantities of Ca inside the SR, but it can also readily release Ca into the cytosol upon the opening of RyR2 channels. At the same time, the free Ca level inside the SR is maintained below the inhibitory level of the SERCA (66). Considering Casq2 properties investigators have speculated that this molecule plays a central role in Ca handling. However, as shown by in vitro studies and genetic mouse models (see sections below), Casq2 not only is an important Ca-buffering protein but it also regulates RyR2 channel open...
Genetic and Clinical Evidence for Casq2 in Arrhythmogenesis

**Genetics.** Catecholaminergic polymorphic ventricular tachycardia (CPVT) is an inherited arrhythmogenic condition with an estimated prevalence in the population of 1 in 10,000. An autosomal-dominant form of CPVT was initially mapped to the chromosomal locus 1q42-q43 where the autosomal-dominant form of CPVT was initially mapped to the *RYR2* gene that changed aspartic acid to an unrelated amino acid. A later study confirmed that the *RYR2* gene is in fact responsible for a dominant inherited CPVT phenotype and that impaired Ca handling is the underlying mechanism of this disease. 

Since *CASQ2*-linked CPVT accounts for 3–5% of all CPVT cases (1), one can estimate the overall prevalence of these homozygous *Casq2* mutations in the general population to be between 1:400,000 and 1:200,000 [similar to the prevalence of LQT syndrome (83)]. The frequency of heterozygous mutation carriers is much higher (1:20,000) and may contribute as added risk in combination with other disorders that cause *RYR2* dysfunction (e.g., heart failure).

Despite the many different *CASQ2* mutations leading to CPVT, the clinical presentation of these patients appears to be more homogeneous than that of *RYR2*-linked CPVT. A possible explanation is provided by studies in knockin mice (discussed below), which showed that all mutations lead to either a severe reduction or complete loss of *CASQ2* protein (80, 88).

Clinical features. Subjects affected by CPVT experience life-threatening ventricular arrhythmia induced by emotional or physical stress in the absence of any structural heart disease. These patients are frequently diagnosed at a young age (9 ± 4 yr) following single or recurrent syncope and/or seizures (75). Other symptoms are light-headedness, dizziness, and palpitations (56). The age at the onset of the first symptoms may vary, and it appears to be related to the severity of the phenotype, with early onset being associated with worse long-term prognosis. The diagnosis of CPVT is not easy, as the physical examination is negative and the resting ECG is normal with a QT interval in the physiologic range. A slight bradycardia is often the only finding observed in these subjects (76). However, that is not specific and CPVT should be suspected in individuals with a personal and/or family history of syncope, seizures, and unexplained sudden cardiac deaths triggered by physical or emotionally stressful activity. The diagnosis can be made with 24-h Holter ECG recording or exercise stress test...
(67). During exercise, patients develop sporadic premature ventricular beats that turn into bigeminal patterns and eventually ventricular tachycardia with higher heart rates (56, 77). A typical ECG finding during exercise or acute emotional stress is bidirectional ventricular tachycardia (BVT), characterized by a beat-to-beat 180° rotation of the QRS complex (Fig. 1D). However, it must be noted that BVT is not pathognomonic of CPVT, because BVT also occurs in acquired conditions such as digitalis toxicity, ischemic heart disease, and myocarditis (10, 27, 89).

Treatment. Early identification and treatment of CPVT patients are very important because of the high mortality of untreated subjects by the time they reach 20 to 30 yr of age (32). The cornerstone of pharmacological treatment of CPVT are β-adrenergic receptor blockers (76). Sequential exercise tests are used to assess the dose and to monitor the efficacy of the treatment. Ca channel blockers, such as verapamil can be used as a second-line treatment in place of a β-blocker or in addition to it in patients who are still symptomatic with the maximum tolerated dose of β-blockers (81, 92). Unfortunately β-blockers and Ca channel blockers are not effective in all the patients, and implantable cardioverter defibrillators (ICD) are frequently used as an additional measure to prevent sudden death. However, ICDs are not always protective because defibrillation shocks can cause catecholamine release and electrical storm, leading to more arrhythmic events; episodes of sudden cardiac deaths in CPVT patients with ICDs have been reported (65, 73, 76). Hence, the need for new pharmacological approaches to CPVT led to the recent observation that the class I antiarrhythmic drug flecainide effectively prevents exercise-induced CPVT in transgenic mice and patients (101), probably because of a dual effect of the drug on Na channels and RyR2 channels that reduces SR spontaneous Ca release and triggered beats (25, 59). In 2011, a clinical case series (97) of 33 CPVT patients unresponsive to conventional drug therapy showed a good response to the class I antiarrhythmic drug flecainide (65, 73, 76). Hence, the need for new pharmacological approaches to CPVT led to the recent observation that the class I antiarrhythmic drug flecainide effectively prevents exercise-induced CPVT in transgenic mice and patients (101), probably because of a dual effect of the drug on Na channels and RyR2 channels that reduces SR spontaneous Ca release and triggered beats (25, 59). In 2011, a clinical case series (97) of 33 CPVT patients unresponsive to conventional drug therapy showed a good response to the class I antiarrhythmic drug flecainide (65, 73, 76). Hence, the need for new pharmacological approaches to CPVT led to the recent observation that the class I antiarrhythmic drug flecainide effectively prevents exercise-induced CPVT in transgenic mice and patients (101), probably because of a dual effect of the drug on Na channels and RyR2 channels that reduces SR spontaneous Ca release and triggered beats (25, 59).

Experimental Evidence from Casq2 Mouse Models

Casq2 gene-targeted mouse models of CPVT. In recent years, studies in transgenic mouse models of CASQ2-linked CPVT have clarified the pathophysiological mechanisms underlying the ventricular arrhythmia as well as identified new therapeutic approaches. In contrast to mouse models of RYR2-linked CPVT, all Casq2 mutant mouse models consistently reproduce the major aspects of human CPVT: exercise and/or emotional stress-induced polymorphic ventricular tachycardia, sinus bradycardia, normal contractility, and normal ECG parameters (76). Table 2 summarizes key findings from the five mouse models currently available: Casq2 homozygous knockout mice (50), Casq2 heterozygous knockout mice (14), Casq2D307H, Casq2R33Q (88), and Casq2R33Q knockin mice (80). Interestingly, all the mutations studied in knockin mice result in either complete loss or severe reduction of Casq2 protein in the jSR. For example, Casq2R33Q is a frame shift mutation that causes a premature stop codon that leads to a truncated, nonfunctional mRNA and loss of Casq2 protein. On the other hand, Casq2D307H knockin mice have normal mRNA levels. However, mutant Casq2D307H protein is almost completely absent (>95% reduction) in the hearts of adult mice, suggesting that the D307H mutation causes enhanced protein degradation or impairs cellular trafficking in vivo (49). In vitro (34) studies suggest that the single amino acid change between the second and third domain of the molecule disrupts the formation of properly oriented dimers and impairs the interactions with triadin and junctin, either of which might contribute to reduced retention of the mature protein in the jSR. Similarly, in Casq2R33Q knockin mice, the mutant protein reaches full maturation but does not form Ca-dependent polymers at physiologic Ca concentrations (5, 45). The defective Casq2R33Q molecule is more susceptible to proteolysis (80), which may explain the drastically reduced levels of mutant Casq2 protein found in this model (Table 2).

Casq2 overexpression mouse models of CPVT. A different approach that gives further insight on the role of Casq2 in CPVT comes from transgenic overexpression of Casq2 carrying the CPVT-linked D307H point mutation using an α-myosin heavy chain promoter either in wild-type or Casq2 knockout mice. In the first report, a chronic increase (from 2- to 6-fold) of mutant Casq2D307H protein in wild-type mice that also have wild-type Casq2 protein produces intracellular changes and in vivo phenotype of catecholamine-induced ventricular arrhythmia (23). This seems to suggest a negative dominant behavior of this mutated protein but is at odds with the human data showing that heterozygous carriers of the D307H mutant are asymptomatic. An explanation may be provided by results obtained by overexpressing Casq2D307H in Casq2 knockout mice that lack Casq2 protein, which model the situation in homozygous human carriers of the D307H mutation. Contrary to the complete loss of mature protein observed in the D307H knockin mice, in this transgenic overexpression model Casq2D307H protein is present at approximately twofold higher concentration than wild-type Casq2 found in nontransgenic littermates. This result suggests that a strong transgenic promoter (α-myosin heavy chain) may be sufficient to overcome the increased protein destruction rate. The mature Casq2D307H displays a folding pattern similar to wild-type Casq2 protein and is also successfully targeted to the jSR cisternae (39). Surprisingly, when expressed at such high levels, the mutant Casq2D307H not only restores the SR ultrastructure compromised in the Casq2 knockout mice but also prevents spontaneous Ca release events in myocytes and almost completely rescues the CPVT phenotype of Casq2 knockout mice (40).
Taken together, these results are consistent with the emerging paradigm that in homozygous carriers of Casq2 point mutations, the severe reduction or complete loss of Casq2 is due to altered trafficking and/or increased protein degradation and is the primary underlying mechanism responsible for the CPVT phenotype. In heterozygous carriers, enough wild-type Casq2 is present to compensate for the high degradation rate of the mutant Casq2 protein and to produce cardiac hypertrophy and reduced contractile function.

**How Does Casq2 Dysfunction Cause Ventricular Arrhythmia?**

**Cellular arrhythmia mechanisms.** Cardiac contractility and systolic Ca releases from the SR appear normal in Casq2 mutant mice at rest. The higher arrhythmogenic risk during stress can be attributed to spontaneous Ca releases from the SR that occur during diastole. The rise in diastolic Ca content is due to spontaneous Ca releases from the SR that can be attributed to spontaneous Ca releases from the SR that occur during diastole. The rise in diastolic Ca content is due to spontaneous Ca releases from the SR that occur during diastole.

RyR2, ryanodine receptor 2; SERCA, sarco(endo)plasmic reticulum Ca\(^{2+}\)-ATPase; CPVT, catecholaminergic polymorphic ventricular tachycardia.
tion activates the Na/Ca exchanger, causing an inward Na current that can result in DAD of the cell membrane and triggered activity (Fig. 1B). Although all cardiomyocytes have the potential to generate a DAD, it has been proposed that DADs occurring in the Purkinje fibers (PF) of the specialized conduction system are the source of the triggered ventricular arrhythmia in CPVT. PF have several characteristics that make them particularly prone for spontaneous Ca releases: decreased T-tubular density (22), the presence of inositol 1,4,5-trisphosphate-sensitive Ca\(^{2+}\) channels (33), and susceptibility to Ca\(^{2+}\) overload (60, 98). An indirect support to this hypothesis is the observation that the drug flecainide, which is effective clinically in CPVT, preferentially suppresses arrhythmogenic Ca waves in isolated PF compared with ventricular myocytes (42).

The PF as the cellular origin of CPVT is supported by experimental evidence in vivo showing conversion of bidirectional VT to monomorphic VT in RyR2 mutant mice after chemical ablation of the right ventricular branch of the conduction system (12). Furthermore, a recent computer model of CPVT reproduced the characteristic ECG pattern of bidirectional VT with a simple “ping pong” mechanism of reciprocating bigeminy between the right and left branches of the conduction system (3). However, based on the computer model, the origin of the bidirectional VT is not restricted to the bundle branches and could also originate from more distal PF or the working myocardium. This is illustrated by recent data from our group, where isolated Casq2 knockout hearts exhibit alternating ventricular activation that originated from the right and left ventricle at sites distinct from the bundle breakthrough points during normal sinus rhythm (Fig. 1C). The resulting bidirectional QRS pattern on the ECG record of the isolated heart (Fig. 1C) was similar to that recorded in vivo using telemetry (Fig. 1D). Thus while the PF are the likely culprit, the exact cellular origin of the bidirectional ventricular arrhythmias remains unknown and is an area of active investigation.

Theoretically, the increased rate of spontaneous Ca releases in Casq2 knockout hearts could produce stochastic membrane DADs that can induce intercellular discordant electrical alternans: when neighboring groups of cells are electrically uncoupled, different repolarization gradients are created in adjacent areas of the heart and they can be a substrate for reentry especially at elevated heart rates (71, 104). However, we (51) recently demonstrated that Casq2 knockout hearts are protected against tachycardia-induced ECG T-wave alternans, which is a marker for susceptibility to reentrant ventricular arrhythmia in animal models and in clinical studies (99). Thus the results from the Casq2 knockout mice suggest that loss of Casq2 causes an increased risk for triggered arrhythmia but may paradoxically protect against reentrant-type arrhythmia.

**Subcellular and molecular arrhythmia mechanisms.** At the subcellular level, we propose at least three independent mechanisms that can explain how reduced or dysfunctional calsequestrin causes the spontaneous SR Ca release events that can trigger ventricular arrhythmia: 1) loss of Ca buffering in the jSR, 2) loss of RyR2 regulation by Casq2, and 3) remodeling of SR structure and proteins. These three mechanisms are discussed in more detail next.

**Loss of Ca buffering in the jSR.** Casq2 is the main Ca-buffering protein of the SR. Both acute as well as chronic overexpression of Casq2 causes a large increase in the SR Ca content (38, 82). Surprisingly, Casq2 homozygous knockout mice display a preserved SR Ca content. Studies on isolated myocytes show that loss of Casq2 Ca-buffering activity was compensated for by a significant (~50%) increase in the SR volume (50). Although the total SR luminal Ca content seems to be preserved, a recent report shows that the kinetics of free Ca in the lumen of the SR are different in Casq2 knockout mice. Loss of Casq2-mediated Ca buffering causes a faster rise in luminal free Ca after each beat (51). The resulting faster rise of Ca near the pore of the RyR2 Ca channels can be expected to have two effects: 1) an increased releasable amount of Ca early during the cardiac cycle, and 2) a faster recovery from SR release refractoriness. Both factors would promote accelerated recovery of SR Ca release, which has recently been confirmed in experiments with intact hearts from Casq2 null mice (51), as shown in Fig. 2. Another consequence of the faster recovery of Ca release in hearts lacking Casq2 is a protection against tachycardia-induced Ca transient alternans and T-wave alternans on ECG, which was significantly reduced in Casq2 knockout mice compared with wild-type hearts (51). Thus Casq2 likely plays a key role in the genesis of Ca transient alternans and T-wave alternans.

**Loss of RyR2 regulation by Casq2.** Regulation of the RyR2 channel permeability appears to be very complex. Both cytosolic and SR luminal free Ca concentration affect the open probability of this channel and influence the duration of the local Ca releases from the SR (52). A large body of evidence supports the concept that SR Ca leak rate is proportional to SR luminal Ca concentration in a nonlinear fashion (62, 86). Loss of Casq2 in Casq2 knockout myocytes makes this relationship much steeper (Fig. 3): in other words, in the absence of Casq2, the SR Ca load threshold at which spontaneous Ca release

![Fig. 2. Casq2 regulates Ca release refractoriness.](https://example.com/fig2.png)
happens is much lower, increasing the overall probability of these events. The same phenomenon is observed in heterozygous Casq2 knockout mice despite the small reduction (~25%) of protein levels in this model and no change in free Ca concentrations in the SR (14, 15). Measurements of free Ca concentrations in the SR lumen of intact hearts lacking Casq2 show that larger SR Ca release can be triggered at the same free intra-SR Ca concentration (51). This result further demonstrates a direct inhibitory role of Casq2 on SR Ca release, which is independent of Casq2’s action as a Ca chelator. The direct inhibitory action of Casq2 on RyR2 is also supported by single RyR2 channel experiments in artificial lipid bilayers (79), and results from studies (38) in cardiomyocytes overexpressing Casq2 that show a significant reduction of both Ca-induced and spontaneous Ca release despite the much higher total SR Ca pool available.

Controversy remains as to whether lack of Casq2 lowers the threshold for luminal or cytosolic activation of Ca release from the RyR2 channel complex (91). In addition, it is uncertain whether this loss of RyR2 regulation is attributable to reduction of Casq2 itself or of the proteins mediating Casq2 binding to RyR2 channels (28). Regardless of the exact mechanism, the net effect is an increased probability of spontaneous Ca release for any given luminal free Ca concentration (Fig. 3).

In this context, any catecholaminergic stress puts further strain on the intracellular Ca handling in CPVT patients. The protein kinase A-mediated effects of the β-adrenergic receptor stimulation lead to an increase in SR Ca load and spontaneous SR releases (43).

REMODELING OF SR PROTEINS AND SR ULTRASTRUCTURE. Almost all Casq2 mutant mouse models studied to date display a significant reduction of the Casq2 binding proteins triadin and junctin (Table 2). Downregulation of triadin and junctin has also been reported in a mouse model of Casq2 overexpression, indicating a possible interdependence of Casq2 and its binding protein expression both in physiologic and pathologic conditions (38). Moreover, gene-targeted deletion of triadin or junctin also generates an arrhythmogenic phenotype in the absence of Casq2 mutations (17, 107). Loss of triadin leads to profound structural modification of the SR (50% reduction of RyR2, Casq2, and junctin) and of the terminal cisternae (up to 50% reduction in the contacts between jSR and t tubules) causing impaired excitation-contraction coupling (17). On the other hand, SR protein expression is not altered in junctin knockout mice although junctin ablation is associated with altered Ca-cycling parameters, and isoproterenol induced DADs (107). Taken together, these findings suggest that the reduction of triadin and junctin may independently contribute to the arrhythmia risk associated with Casq2 mutations (47). Increased protein expression of RyR2, calreticulin, and histidine-rich Ca-binding protein has also been reported in some but not in all of the mouse models (29, 66, 88). However, the relevance of these protein expression changes for the pathogenesis of CPVT remains to be determined. Casq2 knockout mice also compensate for the loss of Casq2 Ca buffering by an increase in SR volume but without significant changes in the jSR cisternae and dyad morphology (50). To what extent the associated changes in SR ultrastructure (e.g., SR volume increase in Casq2 null mice; Ref. 50) contribute to the arrhythmogenic Ca release is not known.

Potential Role of Casq2 in Acquired Arrhythmias

So far, we described the role of Casq2 in CPVT, an inherited arrhythmogenic condition caused by mutations in the Casq2 gene. However, secondary Casq2 dysfunction may contribute to an increased arrhythmia risk in other inherited and acquired cardiac diseases characterized by Ca-handling abnormalities: heart failure, muscular dystrophy, mitochondrial dysfunctions, and drug cardiotoxicity.

Casq2 in heart failure. Heart failure is associated with profound alterations in intracellular Ca handling (9, 102). One consistent finding is an increased SR Ca leak probably facilitated by increased open probability of RyR2 Ca release channels, which, similar to CPVT, increases the risk for spontaneous Ca release under conditions of β-adrenergic stimulation (9, 102). Once spontaneous Ca releases occur, a DAD might be triggered. However, due to an upregulation of the Na/Ca exchanger in failing myocytes, any rise in intracellular Ca results in a greater arrhythmogenic inward current, reducing the quantity of Ca release required to trigger a DAD (74).

Oxidative, PKA and/or CaMKII-dependent modifications of the RyR2 channels during the disease progression have also been implicated in the arrhythmogenic potential of failing hearts by reducing the ability of the RyR2 channels to become refractory after a Ca release (6, 102). Interestingly, Casq2 protein levels are usually unchanged in cardiac tissue from humans and animal models of heart failure. However, investigators have identified posttranscriptional modifications of the Casq2 protein in pacing-induced heart failure models, with a significant change in the mannose content of glycans in Casq2 molecules compared with controls. The structure of the glycan residues observed in this model differs from the one expected in the jSR of healthy cells, suggesting a possible alteration in the metabolism or in the trafficking of Casq2 protein through the secretory compartments (44). These results suggest that Casq2 might be altered by posttranscriptional modifications and never reaches its subcellular target in the jSR (64).

Consistent with this hypothesis, mass spectrometry analysis of Casq2 suggests that higher amounts of Casq2 protein may be
Serious side effect of commonly used drugs such as tricyclic antidepressants, antipsychotic drugs, and anthracyclins. In vitro studies (41) suggest that many of these drugs bind to Casq2 and reduce its Ca-buffering capacity. One of the first experimental evidence suggesting an involvement of Ca-handling abnormalities in the pathogenesis of the drug-induced cardiac damage comes from a rabbit model of doxorubicin-induced cardiomyopathy. After 8 wk of chronic treatment, these animals have reduced levels of SR proteins including RyR2 and Casq2 in the presence of normal levels of Ca ATPase and Na/Ca exchanger (2). In support of this hypothesis is the recent observation that acute administration of antracyclins causes a severe reduction in SR Ca releases most likely through an interaction with Casq2 and oxidation of RyR2 (13, 30).

The tricyclic antidepressant amitriptyline binds to Casq2 at low micromolar concentrations and causes increased spontaneous Ca releases and consequent depletion of the SR Ca content. However, the contribution of drug binding to Casq2 is probably minimal, since the RyR2 hyperactivity results from direct interaction with the RyR2 channel and can be reproduced in myocytes lacking Casq2 (16, 110). Whether amitriptyline binding to Casq2 contributes to cardiotoxicity during long-term exposure is yet to be determined.

Conclusions and Future Developments

The last decade brought a huge progress in our understanding of Casq2-linked CPVT. Basic and translational research on CPVT mouse models have provided information about the intracellular Ca handling and have identified potential drugs for CPVT treatment that have recently been tested in patients with promising results. However, further investigations are needed to clarify the complex interactions among SR proteins that play a central role not only in inherited but also in acquired arrhythmogenic conditions. Future studies will also focus on how cardiac cell subtypes (Purkinje cells and ventricular myocytes in particular) are affected by impaired Ca handling and new treatments developed that specifically target the cell type responsible for CPVT initiation. Finally, the contribution of Casq2 alterations (e.g., altered protein expression levels, genetic variants, and haploinsufficiency in heterozygous carriers of Casq2-null mutations) to arrhythmia risk in ischemic heart disease and/or heart failure will be explored.

GRANTS

This work was supported in part by National Heart, Lung, and Blood Institute Grants H-L8635 and HL-71670 (to B. C. Knollmann), American Heart Association Established Investigator Award 0840071N (to B. C. Knollmann), and the Heart Rhythm Society Fellowship Award (to M. Faggioni).

DISCLOSURES

No conflicts of interest, financial or otherwise, are declared by the author(s).
