Endothelial dysfunction is prevalent in chronic kidney disease. This study tested the hypothesis that transfusion of rat aortic endothelial cells (ECs) ameliorates endothelial dysfunction in a rat model of chronic kidney disease. Male Sprague-Dawley rats underwent sham surgery or 5/6 nephrectomy (Nx). Five weeks after Nx, EC (1.5 × 10⁶ cells/rat) or vehicle were transfused intravenously. One week later, vascular reactivity of mesenteric artery was assessed on a wire myograph. Sensitivity of endothelium-dependent relaxation to acetylcholine and maximum vasodilation were impaired by Nx and improved by EC transfusion. Using selective pharmacological nitric oxide synthase isoform inhibitors, we demonstrated that the negative effect of Nx on endothelial function and rescue by EC transfusion are, at least in part, endothelial nitric oxide synthase mediated. Plasma asymmetric dimethylarginine was increased by Nx and decreased by EC transfusion, whereas mRNA expression of dimethylarginine dimethylaminohydrolases 1 (DDAH1) was decreased by Nx and restored by EC transfusion. Immunohistochemical staining confirmed that local expression of DDAH1 is decreased by Nx and increased by EC transfusion. In conclusion, EC transfusion attenuates Nx-induced endothelial-dependent vascular dysfunction by regulating DDAH1 expression and enhancing endothelial nitric oxide synthase activity. These results suggest that EC-based therapy could provide a novel therapeutic strategy to improve vascular function in chronic kidney disease.

endothelial cell; chronic kidney disease; vascular reactivity; 5/6 nephrectomy; nitric oxide synthase

APPROXIMATELY 14% OF the general population of the United States has chronic kidney disease (CKD). The relationship between CKD and cardiovascular pathology is bi-directional and likely involves alterations in multiple pathways (e.g., traditional cardiovascular risk factors, inflammation, oxidative stress, calcium-phosphorus balance, anemia, and accumulation of uremic toxins) (15). It has been suggested that endothelial dysfunction is the central link that leads to cardiovascular disease in patients with CKD (28, 32). Endothelial dysfunction is a precursor of increased arterial stiffness, atherosclerosis, restenosis after percutaneous coronary intervention, and stenosis of venous bypasses of coronary arteries and of arteriovenous grafts used for dialysis. Studies examining flow-mediated dilation of brachial arteries (35) and vascular reactivity of ex vivo resistance arteries mounted on a wire myograph (26, 29) have demonstrated impaired endothelial function in arteries of patients with CKD.

Endothelial dysfunction in CKD is thought to be related to reduced nitric oxide release secondary to endothelial nitric oxide synthase (eNOS) inhibition by asymmetric dimethylarginine (ADMA) (41). Levels of ADMA, an endogenous low-molecular weight product of protein hydrolysis, are elevated in CKD because of a combination of decreased renal clearance and decreased degradation by dimethylarginine dimethylaminohydrolases (DDAH) (6). An additional contributor to endothelial dysfunction in the setting of CKD is impairment of endothelial repair due to decrease in endothelial progenitor cell count and function (19). We have recently reported the successful use of endothelial cell (EC) transfusion to inhibit inflammation and neointima formation in balloon-injured rat carotid arteries (38). In the present study we tested the hypothesis that systemic transfusion of rat aortic ECs improves endothelial function by increasing eNOS activity in a rat model of CKD.

MATERIALS AND METHODS

Animals and procedures. Male Sprague-Dawley rats were obtained from Charles River Breeding Laboratories, maintained at constant humidity (60 ± 5%), temperature (24 ± 1°C), and light cycle (6 AM to 6 PM), and fed a standard rat pellet diet ad libitum. All protocols were approved by the Institutional Animal Care and Use Committee at the University of Alabama at Birmingham and were consistent with the Guide for the Care and Use of Laboratory Animals, published by the National Institutes of Health.

CKD was induced via renal mass reduction by performing 5/6 nephrectomy (Nx) in two stages. Eleven-week-old rats were anesthetized with 80 mg/kg ketamine and 5 mg/kg xylazine and the upper and lower thirds of the left kidney were surgically resected without renal artery ligation (17). One week later, the right kidney was completely

resected. Sham-operated rats served as controls (Sham). Pilot data showed that serum creatinine progressively increases for 3 wk after Nx and then plateaus at approximately twofold baseline values. Five weeks after Nx, rats were transfused intravenously with normal saline (Nx + Veh) versus 1.5 × 10⁶ rat aortic ECs (Nx + EC).

ECs used in the present study were previously characterized (38). Rat aortic ECs and the EC growth medium MCDB-131C were purchased from VEC Technologies (catalog No. MCDB-131C). No other growth factors were added to the medium. Passage 5 to 6 ECs were transduced with adenoviral vector containing green fluorescent protein (GFP) using the AdEasy Adenoviral Vector System (Strategene) and cultured in 100-mm culture dishes until >80% of cells expressed GFP (1.5 × 10⁶ cells per dish). Cells were washed with 0.9% saline, collected with a cell scaper, dispersed by gentle pipetting, and then concentrated with centrifugation at 100 g and resuspended in 1.5 ml normal saline. The ECs used in this study were shown to express eNOS and DDAH by Western blot analysis. Rats assigned to Nx + EC were transfused through a femoral venous catheter with a total of 1.5 × 10⁶ cells/1.5 ml divided into three doses (0.5 × 10⁶ cells/dose), each separated by 2 h.

Immunohistochemistry. To determine the presence and location of transfused ECs, fresh frozen optimal cutting temperature (OCT)-embedded sections of mesenteric arteries were analyzed for detection of GFP and von Willebrand factor (vWF) using a VECTASTAIN ABC kit (Vector, Burlingame, CA). Sections were treated according to the manufacturer’s instructions using specific antibody against GFP or vWF (Abcam, Cambridge, MA), diluted 1:300 and 1:200, respectively, in 5% normal goat serum/PBS and incubated overnight at 4°C. Sections were then incubated with biotinylated secondary antibody for 30 min followed by incubation with the enzyme conjugate for 30 min, both at room temperature. Immunodetection was determined using a VECTOR NovaRED peroxidase substrate, and the development of reaction product was monitored under a microscope. After color development, sections were washed, counterstained with hematoxylin, and mounted. The chromogen produces a red/brown reaction product at immunopositive sites, whereas cell nuclei stain blue. To quantitate the contribution of transfused ECs versus native ECs to the mesenteric artery endothelium, random sections from mesenteric arteries of seven Nx + EC rats were stained for GFP, and the number of GFP-positive and–negative ECs was counted (total number of counted cells = 999).

To evaluate the effect of Nx and EC transfusion on the local expression of DDAH1 in the endothelium of the mesenteric artery, sections were stained using an anti-DDAH1 antibody (Abcam), diluted 1:300 in conjunction with the VECTASTAIN ABC kit with no counterstaining. Three readers blinded to treatment independently graded sections of arteries from Sham, Nx + Veh, and Nx + EC rats with respect to DDAH1 staining of the endothelium. The grades were averaged for all readers and presented on an arbitrary scale.

Fluorescent imaging. Tissue fresh frozen OCT-embedded sections from mesenteric arteries, liver, lung, spleen, kidney, and heart were examined using a fluorescent microscope imaging system (Nikon TE2000U) with filters set for GFP emission. To detect whether GFP colocalizes with ECs in the mesenteric artery, indirect immunofluorescence staining was carried out, as previously described (12). The sections were blocked with 10% normal goat serum and then incubated with anti-GFP, anti–CD31 (EC marker), or normal mouse/rabbit antibody (1:100, catalog No. TI-1000; Vector Laboratories) for 1 h at room temperature. Nuclei were stained with 4′,6-diamidino-2-phenylindole (DAPI) (50 ng/ml) in PBS for 15 min. Coverslips were washed, mounted with 90% glycerol, and visualized by fluorescence microscopy (×400).

Vascular reactivity. Seven days after EC transfusion, blood pressure was measured in the carotid artery of conscious rats using a polyethylene cannula. Rats were then anesthetized and terminated by open thoracotomy. Blood samples were obtained by cardiac puncture, and the mesentry was collected and placed immediately in ice-cold Krebs-Ringer buffer (KRB) consisting of 118.5 NaCl, 4.7 KCl, 2.5 CaCl₂, 1.2 MgSO₄, 1.2 KH₂PO₄, 25.0 NaHCO₃, and 5.5 glucose. Segments of first-order mesenteric artery were collected by pinning down the mesentry on a 90-mm glass petri dish coated with black Sylgard presoaked in cold KRB. Under a dissecting microscope, the mesenteric arteries were gently cleaned of adipose and connective tissue and cut into segments of 2 mm in length. The mesenteric artery segments were mounted in a wire myograph (model 610M, Danish Myotechnology, Aarhus, Denmark) and placed in myograph chamber filled with 5 ml KRB, maintained at 37°C, and continuously aerated with 95% O₂-5% CO₂ to measure vascular reactivity as previously described (18). With the use of LabChart7 software (ADInstruments, Colorado Springs, CO), each segment was progressively stretched to the diameter at which the largest contractile response to 10 μM norepinephrine could be obtained (referred to as optimal diameter and set to 100% contraction). After a 20-min washout period, a cumulative concentration-response curve (CCRC) to phenylephrine (0.03–30 μM) was obtained. After a second 20-min washout period, the segments were precontracted with phenylephrine (10 μM) until a stable contraction was obtained, followed by a CCRC to the endothelium-dependent muscarinic vasodilator acetylcholine (ACH, 0.001–10 μM). The relaxation responses were recorded in the absence of any pharmacological inhibitors.

To assess the contribution of nitric oxide synthase (NOS) isoforms to endothelial relaxation, mesenteric artery segments were incubated for 30 min with NOS isoform inhibitors, with 30-min washout and resting periods, followed by relaxation responses to ACh (0.001–10 μM) as described above. First, segments were incubated with neuronal NOS (nNOS, N⁵-propyl-l-arginine, l-NPA, 2 μM) (40) and inducible NOS [iNOS, N⁵-[3-(aminomethyl)phenyl]ethyl]methanamide dihydrochloride, 1400W, 10 μM] (10) inhibitors. Second, segments were incubated with eNOS [N⁵-(1-iminomethyl)-l-ornithine HCl, l-nitro, l-NIO, 10 μM] (31) and iNOS (1400W) inhibitors. Finally, segments were incubated with the nonselective NOS inhibitor (N⁵-nitro-l-arginine methyl ester, l-NAME, 100 μM) (31), the soluble guanylate cyclase inhibitor (1H[1,2,4]oxadiazolo[4,3,-α]quinazolin-1-one, ODQ, 10 μM), and the cyclooxygenase inhibitor (indo-methacin, 1 μM).

To study the effect of exogenous ADMA on vascular reactivity, ACh-induced relaxation (0.001–10 μM) of mesenteric arteries from unoperated male Sprague-Dawley rats was assessed in the presence of 100 μM ADMA (Sigma-Aldrich, St. Louis, MO) as previously described (20). Endothelium-independent relaxation was then tested with the nitric oxide donor sodium nitroprusside (0.001–10 μM). ACh, phenylephrine, norepinephrine, l-NPA, l-NIO, 1400W, and l-NAME (Sigma-Aldrich) were dissolved in double distilled water. ODQ (Calbiochem, EMD Millipore, Billerica, MA) was dissolved in DMSO. Indomethacin (Sigma-Aldrich) was dissolved in ethanol. The concentrations of DMSO and ethanol did not exceed 0.1% in the organ bath.

Quantitative real-time polymerase chain reaction. To test the hypothesis that EC transfusion ameliorates CKD-induced endothelial dysfunction via the DDAH-ADMA-eNOS axis, we measured mesenteric artery DDAH1 and eNOS mRNA expression and serum ADMA levels in Sham, Nx + Veh, and Nx + EC rats.

Mesenteric arteries were cleaned of adipose and connective tissue. RNA was extracted using an Ambion PureLink RNA kit (Life Technologies, Grand Island, NY) and quantitated by Nanodrop 2000 spectrophotometer (Thermo Fisher Scientific). Good quality RNA (1 μg) having a ratio of A260/280 > 1.9 was reverse transcribed to cDNA using an Invitrogen SuperScript III kit (Life Technologies), amplified by polymerase chain reaction using Sybr Green master mix (Applied Biosystems) with specific primers for rat DDAH1 (5′-ACGGTGACCCAGCCAGGAT-3′ and 5′-ACTTCCGGCCACT-GAGGGG-3′, Invitrogen) and eNOS (5′GCTCGGGGATGAG-
CAACG-3’ and 5’-GCAGGTCAAAGACGGCAGG-3’) and quantified with the iCycler (Applied Biosystems). Levels of specific mRNAs were normalized by use of reference genes ribosomal protein S9 and 18S, as previously described (5, 14).

Serum creatinine and ADMA and plasma advanced oxidative protein products. Serum creatinine concentration was measured using an liquid chromatography-tandem mass spectrometry (LC-MS/MS) [Waters 2795 separation module (LC)/Micromass Quattro micro API (MS/MS), Analytical Direct, Durham, CT] instrument according to the method described by Young et al. (39). ADMA concentrations were measured using an ELISA kit (MyBioSource, San Diego, CA). Since Nx has been associated with increased oxidative stress (22, 34) and since oxidative stress and eNOS uncoupling are known to induce vascular dysfunction (30), we measured the plasma concentrations of advanced oxidative protein products (AOPPs) that are generated during oxidative stress using the OxiSelect AOPP Assay Kit (Cell Biolab, San Diego, CA).

Data analysis. Contractile responses are expressed as a percentage of the maximal contractile response to 10 μM norepinephrine, whereas relaxation responses are expressed as a percentage relative to maximal contractile response to 10 μM phenylephrine. Individual CCRCs were fitted to a nonlinear sigmoid regression curve (GraphPad Prism 5.0, GraphPad Software, San Diego, CA), and sensitivity (pEC50) and maximal effect (Emax) were calculated. Results are expressed as means ± SEM. Comparisons among experimental groups were performed with one-way ANOVA, followed by Newman-Keuls multiple comparison test when the overall F-test result of ANOVA was significant. Statistical significance was set at P < 0.05.

RESULTS

Renal mass reduction by Nx in male Sprague-Dawley rats resulted in renal dysfunction as assessed by serum creatinine rise. At 6 wk after surgery, serum creatinine increased almost twofold in both Nx groups but remained unchanged from baseline in the sham-operated group (Fig. 1A, P < 0.05). Mean arterial pressure, measured with an invasive carotid artery catheter in conscious rats, was slightly but significantly increased following Nx (118 ± 3 vs. 108 ± 2 mmHg for Nx + Veh vs. Sham, Fig. 1B, P < 0.05). EC transfusion, at 5 wk after Nx, had no significant effect on serum creatinine or blood pressure measured 1 wk later.

Transfused ECs attach to the endoluminal surface of mesenteric arteries and are integrated into the arterial endothelium. At 7 days after intravenous transfusion of GFP-labeled ECs or saline, tissues were harvested, embedded fresh frozen in OCT, and sectioned. On fluorescent microscopy, GFP was not detected in sections from the liver, lung, or heart, but small numbers of GFP-positive cells were seen in the spleen and kidney of Nx + EC rats. GFP was detected on the endoluminal surface of mesenteric arteries of Nx + EC rats and colocalized with CD31 (Fig. 2A). No GFP was detected in sections from Sham or Nx + Veh rats.

Immunostaining for GFP was negative in Sham and Nx + Veh rats. Nx + EC rats showed positive GFP staining in the endothelium of the mesenteric artery (Fig. 2B). vWF staining confirmed that these cells are ECs (Fig. 2C). Sections from large caliber vessels (carotid arteries) showed similar staining (data not shown). Quantitative analysis showed that GFP-positive cells constitute ~13% of ECs of the mesenteric arteries.

EC transfusion ameliorates CKD-induced endothelial dysfunction. Vascular function of segments of first order mesenteric arteries from Sham, Nx + Veh, and Nx + EC rats was assessed using wire myography. There was no significant effect of renal mass reduction or EC transfusion on the contractile reactivity to phenylephrine. The maximal contraction (Emax) to 30 μM phenylephrine [111 ± 3, 117 ± 7, and 112 ± 5% for Sham, Nx + Veh, and Nx + EC, respectively; P = not significant (NS)] and the sensitivity (pEC50) to phenylephrine (0.03–30 μM) (5.20 ± 0.13, 5.26 ± 0.21, and 5.23 ± 0.12, for Sham, Nx + Veh, and Nx + EC, respectively; P = NS) were comparable in the three groups (Fig. 3).

Mesenteric arteries from Nx + Veh rats had severe impairment in endothelium-dependent relaxation in response to ACh compared with Sham controls, with a rightward shift of the CCRC curve (Fig. 4). Sensitivity to 0.001–10 μM ACh (pEC50) averaged 7.21 ± 0.10 in Nx + Veh rats and 8.02 ± 0.06 in Sham controls (Fig. 4, top, right, P < 0.05). Furthermore, mesenteric artery maximal relaxation (Emax) to 10 μM ACh was significantly lower in Nx + Veh rats (79 ± 7%) than in Sham controls (96 ± 2%, Fig. 4, bottom, right, P < 0.05). EC transfusion significantly increased ACh-induced endothelium-dependent vasorelaxation. ACh pEC50 in the Nx + EC group averaged 7.56 ± 0.05, significantly higher than 7.21 ± 0.10 in Nx + Veh group (Fig. 4, top, right, P < 0.05). Emax to 10 μM ACh was also significantly increased in Nx + EC (93 ± 3%, P < 0.05, Fig. 4, bottom, right) versus Nx + Veh (79 ± 7%). Importantly, EC transfusion in Nx rats completely normalized Emax to 10 μM ACh, with no significant difference between Nx + EC and Sham control. Sensitivity to ACh (pEC50) in Nx + EC was significantly lower than in Sham control.
The effect of EC transfusion on CKD-induced endothelial dysfunction is mediated by eNOS. To elucidate the mechanism by which EC transfusion ameliorates CKD-induced endothelial dysfunction, we examined the contributions of the three NOS isoforms to endothelium-dependent ACh-induced relaxation (0.001–10 μM) of mesenteric arteries (Fig. 5). In the Sham control group (Fig. 5, A and B), inhibition of nNOS (with 2 μM L-NPA) and iNOS (with 10 μM 1400W) did not significantly change E\textsubscript{max} to 10 μM ACh. In contrast, inhibition of eNOS (with 10 μM ML-NIO) and iNOS (with 10 μM 1400W) resulted in a significant decrease in E\textsubscript{max} compared with 10 μM ACh alone (65 ± 7% vs. 95 ± 2%, P < 0.05, Fig. 5B). Inhibition of nitric oxide-dependent ACh-induced relaxation using the non-selective NOS inhibitor L-NAME (100 μM) and the soluble guanylate cyclase inhibitor ODQ (10 μM) together with prostacyclin inhibition using the cyclooxygenase inhibitor indomethacin (10 μM) further blunted maximal relaxing responses to ACh (41 ± 7%, P < 0.05 vs. ACh alone and vs. l-NIO + 1400W).

In arteries from Nx + Veh animals, the maximal relaxation response to 10 μM ACh was significantly reduced compared with those from Sham control animals in the presence of nNOS and iNOS inhibition (l-NPA + 1400W) (46 ± 5 vs. 82 ± 4%, P < 0.05, Fig. 5C). EC transfusion abrogated the effect of Nx on the maximal relaxation response to 10 μM ACh (E\textsubscript{max} 78 ± 3% for Nx + EC vs. 46 ± 5 for Nx + Veh, P < 0.05, and P = NS vs. Sham, 82 ± 4%). In contrast, when eNOS and iNOS were inhibited (l-NIO + 1400W), Nx and EC transfusion had no effect on E\textsubscript{max} (65 ± 7% for Sham, 58 ± 12% for Nx + Veh, and 54 ± 6% for Nx + EC, P = NS, Fig. 5D). Similarly, in the presence of l-NAME + ODQ + indomethacin, Nx, and EC transfusion did not significantly change E\textsubscript{max} to 10 μM.
ACh (Fig. 5E). Thus Nx induced and EC transfusion ameliorated endothelial dysfunction only when eNOS was not inhibited, suggesting that the negative effect of Nx on endothelial function and the rescue by EC transfusion are eNOS mediated.

**DISCUSSION**

This study showed for the first time that rat aortic ECs transfused intravenously incorporate into the arterial endothelium of Nx rats and improve small vessel endothelial function. The findings reported here support our hypothesis that transduction of ECs replenishes the damaged endothelium in Nx rats and normalizes elevated systemic ADMA levels, likely by delivering DDAH-1 to the endothelium, releasing inhibition of eNOS, and therefore reversing CKD-induced endothelial dysfunction. This study demonstrates the potential of EC-based therapy as a novel therapeutic strategy to improve vascular function in CKD.

The association between CKD and cardiovascular disease is well established, but the mechanism for this association is not fully understood. Since cardiovascular risk is evident even with mild reductions in renal function (11), the pathophysiological link is presumed to occur at an early stage in the disease process. The endothelium plays a crucial role in maintaining vascular health by regulating vascular tone, hemostasis, inflammatory cell adhesion, and migration into the vessel wall, platelet activity, and angiogenesis (37). Studies have demonstrated endothelial dysfunction in arteries of patients with both early and advanced-stage CKD, but these studies were often confounded by increases in traditional risk factors, which are independently associated with abnormalities in endothelial function (e.g., diabetes mellitus and hypertension) (28). Studies that have demonstrated endothelial dysfunction in animal models of CKD have also been confounded by the development of severe hypertension in the setting of CKD (36). We used a CKD renal mass reduction model that avoids renal infarction by directly resecting renal tissue. Consistent with previous studies that used this model (1), we observed only slight elevations in systemic blood pressure (mean, 10 mmHg), and the blood pressure of Nx animals remained in the normotensive...
range. In the absence of hypertension, CKD was associated with endothelial dysfunction with severe impairment in ACh-induced endothelium-dependent relaxation. Furthermore, we have demonstrated that CKD-induced endothelial dysfunction is dependent on eNOS (Fig. 5). In sham-operated control rats, pharmacological inhibition of nNOS and iNOS did not inhibit endothelium-dependent maximum relaxation, whereas inhibition of eNOS did. Moreover, EC transfection rescued the endothelial dysfunction caused by Nx when nNOS and iNOS were inhibited (but eNOS was not) but had no effect on endothelial function when eNOS was inhibited. Interpretation of these data is limited by the incomplete selectivity of the inhibitors of the NOS isoforms. For example, although L-NIO is considered a selective inhibitor of eNOS, it inhibits to a lesser degree both nNOS and iNOS (3). Furthermore, there was a statistically nonsignificant trend toward inhibition of ACh-induced vasodilation with L-NPA, and L-NIO + 1400W did not completely inhibit ACh-induced vasodilation. This suggests that nNOS may also be involved in this process, as recently shown (33, 34).

Patients with CKD have markedly decreased numbers of circulating endothelial progenitor cells compared with healthy volunteers (7, 8, 23). Endothelial progenitor cells contribute to vascular integrity by homing to sites of vascular injury and incorporating into the endothelium (9). In addition to their decreased number, progenitor cells derived from CKD patients have functional impairment, including impaired migratory function in response to vascular endothelial growth factor, decreased adherence to fibronectin-coated diureido-pyrimidinone-polycaprolactone, decreased incorporation into EC vascular structures in culture (Matrigel tube formation assay), reduced endothelial outgrowth potential, and reduced antithrombogenic function (7, 23). A recent study by Lorenzen et al. (25) of 265 patients with end-stage CKD demonstrated that reduction in functionally active endothelial progenitor cells is an independent predictor of incident cardiovascular events over a median follow-up period of 36 mo. Taken together, these studies suggest that CKD is associated with impairment of endogenous capacity to repair the vasculature. When combined with increased endothelial injury in CKD, this results in an imbalance that favors endothelial dysfunction (19). Local delivery of endothelial progenitor cells to balloon-injured arteries with denuded endothelium has been shown to accelerate endothelialization and improve endothelium-dependent vasoreac-
Our current data show that the administration of EC to Nx rats replenishes ADMA level (11) and local expression of DDAH1 by immunohistochemistry (IHC, protein) (8) in Sham, Nx + Veh, and Nx + EC are shown. C: exogenous ADMA (100 µM) inhibits ACh-induced relaxation (0.001–10 µM) of mesenteric arteries but not endothelium-independent relaxation tested with the nitric oxide donor sodium nitroprusside (SNP; 0.001–10 µM). D: oxidative stress, measured as serum level of advanced oxidative protein products (AOPPs) in rats at 7 days after transfusion of ECs or vehicle indicates that Nx is associated with increased oxidative stress and that EC transfection lowers AOPP levels. The numbers above the bars indicate the number of mesenteric arteries analyzed in each group. P < 0.05 by ANOVA for all graphs. *P < 0.05 vs. Sham; #P < 0.05 vs. Nx + Veh. AU, arbitrary units.

In conclusion, the studies described here provide the framework for novel therapeutic interventions that use cell therapy that homes to the endoluminal surface of the vasculature to deliver DDAH1 locally to the endothelium to reverse CKD-induced endothelial dysfunction.
