Submitted 19 May 2014; accepted in final form 11 December 2014

Wang Y, Braun OÖ, Zhang S, Norström E, Thorlacius H. Monocytes regulate systemic coagulation and inflammation in abdominal sepsis. Am J Physiol Heart Circ Physiol 308: H540–H547, 2015. First published December 12, 2014; doi:10.1152/ajpheart.00336.2014.—Abdominal sepsis is a leading cause of hospital-related deaths (3, 16). Sepsis-induced mortality ranges between 18% and 30%, and the presence of disseminated intravascular coagulation increases the mortality rate to 35% (8, 13, 31). The high mortality rate in septic patients is in part related to an incomplete understanding of the underlying pathophysiology. Intestinal contamination of the abdominal cavity with toxins and microbes causes local formation of proinflammatory substances, such as cytokines and chemokines (18). Translocation of microbes, toxins, and proinflammatory substances into the circulation triggers a systemic inflammatory response characterised by widespread activation of innate immune cells, such as monocytes and neutrophils, leading to organ injury (5, 28). Several studies have shown that pulmonary recruitment of neutrophils is a rate-limiting step in septic lung injury (9, 11). Neutrophils are particularly sensitive to C-X-C motif (CXC) chemokines, including chemokine CXC ligand (CXCL)1, CXCL2, and CXCL5, pulmonary activity of myeloperoxidase, thrombin generation, and coagulation factors were determined 6 h after CLP induction. Administration of clodronate liposomes decreased circulating levels of monocytes by 96%. Time to peak thrombin formation was increased and peak and total thrombin generation was decreased in plasma from CLP animals. Monocyte depletion decreased time to peak formation of thrombin and increased peak and total generation of thrombin in septic animals. In addition, monocyte depletion decreased the CLP-induced increase in the levels of thrombin-antithrombin complexes in plasma. Depletion of monocytes increased plasma levels of prothrombin, factor V, factor X, and protein C in septic mice. Moreover, depletion of monocytes decreased CLP-induced levels of IL-6 and CXC chemokines in the plasma and lung by >59% and 20%, respectively. CLP-induced myeloperoxidase activity in the lung was attenuated by 44% in animals depleted of monocytes. Taken together, our findings show, for the first time, that peripheral blood monocytes regulate systemic coagulation. The results of our study improve our understanding of the pathophysiology of sepsis and encourage further attempts to target innate immune cell functions in abdominal sepsis.

While several studies have shown that pulmonary recruitment of neutrophils is a rate-limiting step in septic lung injury (9, 11), neutrophils are particularly sensitive to C-X-C motif (CXC) chemokines, including chemokine CXC ligand (CXCL)1, CXCL2, and CXCL5 (20). Although it is widely held that monocytes play an important role in systemic inflammation, the literature on the role of monocytes in controlling pulmonary neutrophilia is complex and partly contradictory (1, 35). Thus, we decided to examine the role of blood monocytes for pulmonary accumulation of neutrophils as well as cytokine and chemokine formation in abdominal sepsis.

Hemostatic dysfunction is one of the most prominent features in sepsis. Hemostatic alterations in sepsis are typified by an early hypercoagulable phase concomitant with impaired anticoagulation and fibrinolysis (33). This is followed by a hypocoagulable phase due to consumption of platelets and coagulation factors (41). Hemostatic cascades are complex processes consisting of a dynamic interplay between several discrete elements (23, 30). Individual quantification of these elements by classical assays, including the ones used to measure coagulation factors and inhibitors, do not capture the global effect of all these elements in hemostasis (34). Instead, global hemostasis assays, including thrombin generation tests and thromboelastometry, have emerged as effective tools to obtain more comprehensive evaluations of hemostasis (10, 32). Thrombin generation has been shown to be useful in the evaluation of diseases with complex changes in hemostasis, such as chronic liver disease (37), trauma-induced coagulopathy (12), and liver transplantation (15). Recent clinical studies have shown that thrombin generation is greatly diminished in patients with sepsis (4, 26). In the present study, we hypothesized that monocytes might play a role in regulating thrombin generation and coagulation factor consumption in sepsis.

Based on the considerations above, the aim of the present study was to define the role of monocytes in regulating systemic inflammation and coagulation in abdominal sepsis. For this purpose, we used a sepsis model based on ligation and puncture (CLP) procedure as previ-
ousley described in detail (40). Briefly, animals were anesthetized, and a midline incision was made to expose the cecum, which was filled with feces by milking stool backward from the ascending colon. The cecum was then ligated with a 5-0 silk suture. The cecum was soaked with PBS (pH 7.4) and punctured twice with a 21-gauge needle on the antimesenteric border. The cecum was returned into the peritoneal cavity, and the abdominal incision was sutured. Sham mice underwent identical laparotomy and resuscitation procedures, but the cecum was neither ligated nor punctured. Animals were reanesthetized 6 h after CLP to collect samples for further analysis.

Monocyte and neutrophil depletions. Mice were administered intraperitoneally with 20 mg/kg clodronate liposomes (Encapsula Nano Sciences) 24 h before CLP, and animals treated with PBS liposomes served as controls. An antibody directed against lymphocyte antigen (Ly)6G (20 mg/kg, clone 1A8, Bioxcell, West Lebanon, NH) was given intraperitoneally 24 h before CLP to deplete animals of neutrophils. Control animals received a control antibody (20 mg/kg, Bioxcell).

Flow cytometry. Blood was collected into syringes containing 1:10 acid citrate dextrose 6 h after CLP induction. Blood samples were incubated with an anti-CD16/CD32 antibody (10 min at room temperature), which blocked Fcγ III/II receptors, to reduce nonspecific labeling and then incubated with FITC-conjugated anti-Mac-1 (clone M1/70, BD Pharmingen, San Jose, CA), phycocerythrin-conjugated anti-Ly6G (clone 1A8, BD Pharmingen), and phycocerythrin-Cy-conjugated anti-Ly6C (clone AL-21, BD Pharmingen) antibodies. Leukocytes were recovered after centrifugation. Flow cytometric analysis was performed according to standard settings on a FACSCalibur flow cytometer (Becton Dickinson, Mountain View, CA), and a viable gate was used to exclude dead and fragmented cells. Monocytes were defined as Ly6C<sup>+</sup>/Ly6G<sup>−</sup> cells.

Myeloperoxidase activity. Myeloperoxidase (MPO) levels in lung tissue were assayed according to a standard protocol (38). Briefly, frozen tissue was thawed and homogenized in 0.02 M phosphate buffer (pH 7.4). The supernatant was discarded after centrifugation for 10 min at 14,000 rpm at room temperature, and the pellet was then dissolved by adding 1 ml of 0.5% hexadecyltrimethylammonium bromide. Samples were stored at −20°C overnight, thawed, and then kept at 60°C in a water bath for 2 h followed by 90-s sonication. The supernatant was collected after 5 min of centrifugation at 14,000 rpm, and MPO activity in the supernatant was determined spectrophotometrically as the MPO-catalyzed change in absorbance in the redox reaction of H₂O₂ (450 nm, with a reference filter of 540 nm, 25°C). Values are expressed as MPO units per gram of tissue.

Systemic leukocyte and platelet counts. Blood was collected from the tail vein and mixed with Turks solution [0.2 mg gentian violet in 1 ml glacial acetic acid, 6.25% (vol/vol)] in a dilution of 1:20 for the quantification of polymorphonuclear and mononuclear leukocytes or with stromatol solution (Mascia Brunelli Spa, Viale Monza, Milan, Italy) in a dilution of 1:500 for the identification of platelets in a Burker chamber.

ELISA. Plasma levels of prothrombin, factor V, factor VII, factor X, activated protein C, and thrombin-antithrombin (TAT) complexes were quantified using commercially available ELISA kits (Molecular Innovations, Peary Ct, Novi; USCN Life Science, Wuhan, Hubei, China; and Siemens, Marburg, Germany). Both plasma and lung tissue levels of IL-6 as well as CXCL1, CXCL2, and CXCL5 were determined by commercial ELISA kits (R&D Systems, Abingdon, Oxon, UK). Lungs were harvested 6 h after the induction of CLP and immediately frozen at liquid nitrogen. Blood samples were collected 6 h after the induction of CLP from the vena cava (1:10 acid citrate-dextrose), centrifuged at 14,000 rpm for 10 min at 4°C, and stored at −20°C until use. Linearity was assessed and confirmed by samples containing recombiant mouse prothrombin factor V, factor VII, factor X, activated protein C, IL-6, CXCL1, CXCL2, CXCL5, and TAT standard plasma serially diluted with a calibrator diluent.

**Thrombin generation assay.** For analysis of thrombin generation, mouse blood was collected from the inferior vena cava (1:10 acid citrate-dextrose). As previously described (6), platelet-poor plasma was obtained by a series of centrifugations to remove platelets and cell fragments. Samples were first centrifuged at 19,000 g for 15 min and then at 20,500 g for 40 min to obtain platelet-poor plasma. Phospholipid vesicles containing 10% phosphatidyl serine, 20% phosphatidylethanolamine, and 70% phosphatidylcholine were prepared by extrusion as previously described (22). Recombinant mouse tissue factor was obtained from R&D Systems. The fluorogenic substrate Z-Gly-Gly-Arg-AMC was obtained from Bachem (Bubendorf, Switzerland). A working solution of recombinant mouse tissue factor (1 PM) was prepared in HEPES-buffered saline solution containing 25 mM HEPES, 140 mM NaCl, and 5 mM/ml BSA, and a mixture of fluorogenic substrate (0.3 mM) and CaCl₂ (16 mM) was freshly prepared in HEPES-buffered saline. To start thrombin generation, 10 μl phospholipid vesicles (0.5 mM), 40 μl platelet-poor plasma, 10 μl tissue factor, and 20 μl fluorogenic substrate with CaCl₂ were mixed. The formation of thrombin was monitored with accumulated fluorescence in a Tecan Infinite 200 microplate reader (Männedorf, Switzerland) at an excitation wavelength of 360 nm and emission wavelength of 460 nm. All experiments were carried out in duplicate at 37°C.

**Statistics.** Data are presented as means ± SE; n represents the number of animals. Statistical evaluations were performed using Kruskal-Wallis one-way ANOVA on ranks followed by multiple comparisons versus the sham group (Dunnett’s method). P values of <0.05 were considered statistically significant.

**RESULTS**

Monocyte depletion and activation. Clodronate liposomes were used to deplete mice of monocytes as previously described (22). Intraperitoneal administration of clodronate liposomes decreased the circulating number of monocytes by 96% (Fig. 1, A and B). Treatment with clodronate liposomes had no other effect on any leukocyte subtype (data not shown). To study whether monocytes are activated in the CLP model, we examined CD11b levels on circulating monocytes and found a clear-cut increase in monocyte expression of CD11b in septic animals (Fig. 1, C and D).

Monocytes regulate thrombin generation. CLP significantly increased time to peak formation by 134%, reduced peak formation by 71%, and decreased total thrombin generation by 57% (Fig. 2, A–D). Monocyte depletion significantly reduced time to peak thrombin formation and restored peak and total thrombin generation back to levels similar to those in sham animals (Fig. 2, A–D). TAT complexes formed after neutralization of thrombin by antithrombin III have been used as a surrogate marker for thrombin generation (39). In the present study, we observed that CLP markedly increased plasma levels of TAT complexes and that the administration of clodronate significantly reduced CLP-induced TAT complex levels in plasma by 54% (Fig. 3).

Monocytes regulate consumption of coagulation factors. CLP caused a significant decrease in plasma levels of prothrombin (Fig. 4A), factor V (Fig. 4B), factor X (Fig. 4C), and protein C (Fig. 4D). We found that plasma levels of prothrombin, factor V, factor X, and protein C were markedly higher in septic mice depleted of monocytes compared with CLP animals treated with vehicle (Fig. 4, A–D).

Neutrophil infiltration in the lung. Systemic inflammation in abdominal sepsis is characterized by the accumulation of neutrophils in the lung. Indeed, we found that CLP triggered a 5.4-fold increase in pulmonary activity of MPO, a marker of
neutrophils (Fig. 4). Depletion of monocytes reduced CLP-induced MPO activity by 44% in the lung (Fig. 4). Administration of the anti-Ly6G antibody decreased circulating numbers of neutrophils by 90% (Table 1 and Fig. 5B). Depletion of neutrophils decreased CLP-induced MPO levels in the lung by 82% (Fig. 5A).

Systemic levels of IL-6 and CXC chemokines. CLP increased plasma levels of IL-6 by 1,214-fold and pulmonary levels of IL-6 by 15-fold (Fig. 6A). Monocyte depletion attenuated levels of IL-6 by 66% and 39% in the plasma and lung, respectively, in septic animals (Fig. 6A). In addition, CLP markedly enhanced CXCL1, CXCL2, and CXCL5 levels in the plasma and lung (Fig. 6, B–D). We found that depletion of monocytes significantly reduced plasma and lung levels of CXCL1, CXCL2, and CXCL5 in CLP mice (Fig. 6, B–D).

Fig. 1. Monocyte depletion and activation. Sham-operated animals treated with PBS liposomes (A) and clodronate liposomes (B). C: circulating monocytes from sham (dashed line) and CLP animals (solid line) were stained with a control antibody and anti-Mac-1 antibody 6 h after the induction of CLP. The histogram shows Mac-1 expression on monocytes. D: aggregate data on monocyte expression of Mac-1 in sham and CLP mice. Monocytes were defined as Ly6C<sup>+</sup> and lymphocyte antigen (Ly)6G<sup>-</sup> cells using flow cytometry. Data are means ± SE; n = 5. *P < 0.05 vs. the sham group.

Fig. 2. Monocytes regulate thrombin generation in abdominal sepsis. Plasma samples were harvested 6 h after CLP induction. Animals were treated with PBS liposomes or clodronate liposomes before CLP induction. Sham animals served as negative controls. A–D: thrombin generation over time (A), time to peak formation (B), peak levels (C), and total thrombin generation (D) were determined as described in MATERIALS AND METHODS. Data are means ± SE; n = 5. *P < 0.05 vs. the sham group; #P < 0.05 vs. the PBS + CLP group.
DISCUSSION

Systemic changes in inflammation and coagulation are key components in sepsis. This study documents an important role of peripheral blood monocytes for sepsis-induced thrombin generation and consumption of coagulation factors. Moreover, our findings show that monocytes are critical for the formation of proinflammatory compounds and neutrophil accumulation in the lung in abdominal sepsis. These results increase our understanding of the important role of monocytes in the pathophysiology of sepsis.

Convincing evidence has demonstrated that neutrophil recruitment is a rate-limiting step in the pathophysiology of septic lung injury (5, 28). It is generally held that monocytes/macrophages play a central role in the host response against bacterial infections, although the published data on the role of monocytes/macrophages for pulmonary neutrophilia are complex and contradictory. For example, on the one hand, one study (35) reported that alveolar macrophages are a positive regulator endotoxin-induced neutrophil accumulation in the lung. On the other hand, another study (2) has shown that depletion of alveolar macrophages has no effect or even increases pulmonary recruitment of neutrophils in response to endotoxin (2). Similarly, in a similar model of ischemia-reperfusion-induced lung injury, one report (22) showed that depletion of alveolar macrophages decreased neutrophil infiltration, whereas another study (1) demonstrated that depletion of alveolar macrophages increased neutrophil accumulation in the lung. In the present study, we observed that CLP increased surface expression of Mac-1 on circulating monocytes, indicating that monocytes are activated in this model of abdominal sepsis. Moreover, we found that depletion of peripheral blood monocytes decreased CLP-induced pulmonary activity of MPO by 44%, suggesting that blood monocytes are important regulators of neutrophil recruitment in septic lung injury. This notion is in line with two previous studies (7, 19) on endotoxin-induced neutrophil accumulation in the lung showing that blood monocytes rather than alveolar macrophages control neutrophil infiltration in the inflamed lung. In addition, our findings are corroborated by a previous study (36) showing that clodronate protects against hepatic accumulation of neutrophils and tissue damage in a model of septic peritonitis. Moreover, our findings show that blood monocytes are important regulators of plasma and lung levels of CXCL1, CXCL2, and CXCL5 in abdominal sepsis. Knowing that these CXC chemokines are potent activators and chemoattractants of neutrophils (42, 43), it may be forwarded that blood monocyte-dependent formation of CXC chemokines is one mechanism by which blood monocytes control neutrophil activation and accumulation in septic lung injury. In this context, it should be mentioned that systemic administration of clodronate might also deplete other cells, such as Kupffer cells and alveolar macrophages, that could contribute to the effects of clodronate.

Patients with sepsis are characterized by progressive dysfunction of hemostasis typified by consumption of plate-
lets and coagulation factors causing a state of hypocoagulation. Previous studies on the hemostatic response in sepsis have mainly been based on analyses of individual elements of the coagulation system, which may not capture the net effect of sepsis on hemostasis. Instead, more recent efforts have been focused on global tests of hemostasis, such as thromboelastometry and thrombin generation (10, 32). Of these tests, thrombin generation has been most extensively used to characterize complex coagulopathies (29). In the present study, we found that abdominal sepsis markedly attenuated thrombin generation, which is in line with four recent clinical reports on patients with sepsis (4, 17, 26, 27). Knowing that tissue factor is a potent stimulator of thrombin formation in vitro and that monocyte-derived tissue factor is the dominating source of intravascular tissue factor in sepsis (24), it was of great interest to examine the role of blood monocytes for thrombin generation in abdominal sepsis. In the present study, we found that depletion of blood monocytes decreased time to peak generation of thrombin as well as increased peak and total thrombin formation in CLP animals, showing, for the first time, that blood monocytes regulate thrombin generation in abdominal sepsis. This conclusion is also supported by our findings showing that clodronate markedly reduce the enhanced plasma levels of TAT in septic animals. Interestingly, a previous study (25) showed that endotoxin-induced activation of the coagulation system is dependent on myeloid (granulocytes and monocytes) cell-derived tissue factor. Whether the monocyte-dependent formation of thrombin in abdominal sepsis observed here is mediated by tissue factor is a topic for further studies.

A common observation in patients with sepsis is a progressive loss of coagulation factors in plasma. We next examined the role of monocytes in sepsis-induced consumption of coagulation factors. We observed that CLP induction reduced plasma levels of prothrombin, factor V, and factor X as well as protein C by 57%. Notably, depletion of

Monocytes restored plasma levels of these factors in septic animals, suggesting that monocytes play a central role in the consumption of coagulation factors in abdominal sepsis. In this context, it is interesting to note that among its many activities, IL-6 has been shown to exert a pivotal role in hemostasis. For example, IL-6 can induce a prothrombotic state by increasing platelet production and reactivity as well as promoting expression of tissue factor and coagulation factors (14). Indeed, one recent study (21) has demonstrated that IL-6 can increase thrombin generation. In the present study, we found that the induction of CLP triggered increased plasma levels of IL-6 and that monocyte depletion abolished the sepsis-evoked increase in IL-6 production. These findings suggest that monocytes are important for increased formation of IL-6 in sepsis and could help to explain, at least in part, the monocyte-dependent activation of systemic coagulation as observed in the present study.

Taken together, our novel results demonstrate that blood monocytes regulate both systemic coagulation and inflammation in abdominal sepsis. These findings help elucidate the role of monocytes in the pathophysiology of sepsis and encourage further attempts to target monocytes to ameliorate hemostatic dysfunction and pathological inflammation in abdominal sepsis.
