TRANSLATIONAL PHYSIOLOGY

Autonomic control of the heart is mediated by complex interactions between peripheral and central aspects of the cardiac nervous system (4, 7, 75). These interactions are modulated by nested feedback loops to promote optimal cardiac output under a wide variety of environmental conditions and stresses (7). Myocardial infarction (MI) induces profound changes within this hierarchy, from the level of the heart to the central nervous system that regulates its performance (6, 11, 75). Neurohumoral interactions are likewise altered by MI, including upregulation of the renin-angiotensin-aldosterone system and circulating catecholamines, both of which contribute to the progression of heart failure (23, 32, 37). Cardiac myocyte structure and function are also affected by MI; such changes include apoptosis (17), changes in the collagen matrix (24), and induction of electromechanical dyssynchrony, which is associated with altered ventricular contractile function (3, 55).

Recent work from our laboratory demonstrated time-dependent changes in the intrinsic cardiac (IC) neurons after MI. Specifically, in the 1st wk post-MI, IC neurons demonstrate an increased excitability and sensitivity to norepinephrine (NE), reduced sensitivity to both the muscarinic agonist bethanechol and Ang II, and increased network synaptic efficacy (36). Longer term (2 mo) MI-induced changes within the IC neuronal plexus include a return of synaptic efficacy toward baseline values in association with increases in IC neuronal nitric oxide synthase, local mast cell density, and increased neuronal responsiveness to histamine (36, 38).

Whereas the cardiac nervous system is optimized to respond to everyday stressors (orthostatic, heat, exercise, emotion), it can be critically disrupted by the stress of myocardial ischemia/infarction (6, 47), sometimes with lethal effects (11, 13). As a consequence of MI, the IC nervous system (ICNS), the final convergence point for cardiac neural control, is subjected to altered afferent inputs, as well as changes in descending neuronal inputs that include reflex-induced sympatho-excitation and reduced central drive from the parasympathetic nervous system (7, 11, 22).

We have previously demonstrated that chronic MI alters IC neurons, thereby increasing IC neuronal plexus excitability leading to cardiac dysfunction (36, 38). It is known that beta-adrenergic blockade and pharmacological modulation of

NEW & NOTEWORTHY

The major finding of this study is that autonomic regulatory therapy, using vagus nerve stimulation, mitigates myocardial infarction-induced remodeling of the intrinsic cardiac nervous system, correspondingly preserving ventricular contractile function via both neural and cardiomyocyte-dependent actions.
angiotensin AT1 and AT2 receptors can attenuate such remodeling (33, 37, 39). We have demonstrated further that neuro-modulation therapy, using spinal cord stimulation, is effective in blunting ischemia-induced reflex excitation of extracardiac and IC neurons (5, 9), thereby mitigating the ischemia-induced arrhythmogenic substrate (16) and reducing cardiomyocyte cell death (63, 64). Vagus nerve stimulation (VNS) activates both ascending (afferent) and descending (efferent) axons that course in the vagus (12, 14), thereby impacting central and peripheral aspects of the cardiac nervous system. In either case, IC neurons represent the final convergence point for parasympathetic neural-cardiac control (7, 45).

Given the above, we hypothesize that restoration of an exogenous, biomimetic, “central” parasympathetic drive via cervical VNS will mitigate remodeling of IC neurons and render cardiac myocytes stress resistant. Together, these effects of VNS will mitigate progression of cardiac dysfunction post-MI. This hypothesis is further predicated on the antiadrenergic responses that are elicited by parasympathetic efferent neuronal inputs acting at processing nodes within the cardiac nervous system and at the efferent neural-myocyte interface (11, 50, 54).

To evaluate this hypothesis critically, we examined cardiac function in vivo via echocardiography in animals with chronic MI, either in the absence or presence of chronic VNS therapy, to determine the following: 1) how such therapy impacts IC neuronal transmembrane electrical properties, 2) their interactive synaptic efficacy in vitro, and 3) the capacity of such therapy to induce a cardioprotective state at the myocyte level. As such, we were able to assess the therapeutic benefits of VNS therapy, not only at the cardiomyocyte level but also how it impacts IC neurons that regulate cardiomyocyte behavior.

MATERIALS AND METHODS

All procedures were approved by the Institutional Animal Care and Use Committee of East Tennessee State University and were in accordance with the Guide for the Care and Use of Laboratory Animals, Eighth Edition, published by The National Academies Press.

Implantation of VNS systems. Eighteen male Hartley guinea pigs (Charles River Laboratories, Wilmington, MA), weighing between 500 and 650 g (9 wk old), were implanted with a VNS system comprised of a pulse generator and bipolar lead. Under aseptic conditions, animals were pretreated with atropine (0.1 mg/kg sc) and ketamine (80 mg/kg ip). Thereafter, anesthesia was induced with 3% isoflurane via an induction chamber (VetEquip, Pleasanton, CA). Upon removal from the induction chamber, 2.5% isoflurane was delivered via a conical nose cone (VetEquip) until responses to isoflurane via an induction chamber (VetEquip, Pleasanton, CA). Ketamine (80 mg/kg ip). Thereafter, anesthesia was induced with 3% isoflurane via an induction chamber (VetEquip, Pleasanton, CA).Buprenorphine (0.05 mg/kg sc), given as needed, and cefazolin (30 mg/kg im) for 7 days. The pulse generator was inactive for the recovery period (~2 wk).

Surgical induction of heart disease. Two weeks later, using techniques detailed previously (36, 38), MI was surgically induced by ligation of the ventral descending coronary artery and associated vein in all 18 guinea pigs equipped with a VNS system. Anesthesia and postoperative care were the same as described above. Work from our laboratory (36, 38) and others (18) has shown that such methodology induces an ~8% infarct. Of 18 animals, two died early on as a direct result of MI, and two were euthanized secondary to necrosis surrounding the pulse generator. Of the remaining 14 animals, following 1 wk of MI recovery, animals were randomized to groups that were either stimulated (VNS-MI group; n = 7) or not stimulated (MI control group; n = 7). All VNS-MI animals were treated with chronic, intermittent (continuously cyclic), low-intensity right cervical VNS (20 Hz pulse frequency, 0.9 ± 0.2 mA pulse amplitude, 500 μs pulse duration, 14 s on time, 48 s off time for 80 days). Age-matched animals without surgery were used as concurrent controls (control group, n = 8).

VNS stimulation parameters were chosen to be close to the neural fulcrum, where any effects on heart rate were minimized by the relative effects of VNS on afferent- and efferent-dependent responses (45). One-third of the animals demonstrated a 5% evoked bradycardia during active-phase VNS. Fifty percent of animals exhibited no significant change in heart rate with VNS. Two animals exhibited a slight tachycardia during active-phase VNS. VNS intensity levels are limited in the guinea pig by effects on water and food intake. In the animals that did not exhibit bradycardia, attempts to increase stimulus intensity further resulted in loss of body weight.

Echocardiography. Following sedation with isoflurane (1–2% via nose cone), short-axis and long-axis echocardiograms were used to determine the left ventricular end systolic volume (LVESV) and the LV ejection fraction (LVEF) for each animal. These measurements were acquired before VNS implant surgery and at 90 days post-MI, just before the terminal experiment.

Terminal experiments. Following echocardiography, animals were euthanized by CO2 inhalation and exsanguination. The heart was removed and placed into ice-cold Krebs-Ringer solution (in mM: NaCl 121, KCl 5.9, CaCl2 2.5, MgCl2 1.2, NaH2PO4 1.2, NaHCO3 25, glucose 8, aerated with 95% O2/5% CO2 for a pH of 7.4). The heart and lungs were weighed. The lungs were dried at 37°C and weighed again (dry lungs). The cardiac nerve plexus, located in the epicardium of the atrial walls, was dissected as described previously (35). Following dissection, tissue was superfused continuously (6–8 ml/min) with 35–37°C Krebs-Ringer.

Electrophysiological methods. Intracellular voltage recordings from IC neurons were obtained with an Axoclamp 2B amplifier (Molecular Devices, Sunnyvale, CA) from cells impaled with 3 M KCl-filled glass micropipettes (40–80 MΩ). In the guinea pig model, the IC neurons, recorded with such sharp microelectrodes, are primarily cholinergic in nature (52). Data were collected, digitized, and analyzed using pCLAMP 10.2 (Molecular Devices). Individual neurons were used for data analysis if the resting membrane potential (RMP) was ~40 mV or less and produced action potentials with an overshoot of at least 20 mV (31). Single action potentials were produced by brief depolarizing current injections (0.7–1.2 nA, 3 ms). Six individual traces were averaged and analyzed to determine afterhyperpolarization (AHP) amplitudes and durations. AHP durations were analyzed to determine the time needed to reach 50% of the amplitude from the peak of the AHP to the RMP. Neuronal input resistance was determined by injecting small hyperpolarizing current pulses of 0.1 and 0.2 nA using 500 ms pulse duration. Neuronal excitability was monitored by observing the number of action potentials generated in response to a series of long depolarizing current pulses (0.1–0.6 nA, 500 ms) before and after brief (1 s) application of NE 10–8 M (Sigma, St. Louis, MO), applied by local pressure jet (4–6 psi; Picospritzer II; General Valve, Fairfield, NJ) through a small tip diameter (5–10 μm) glass micropipette, positioned 50–100
RESULTS

Echocardiography was performed on each animal before MI (baseline) and compared with the data acquired at day of termination (cf. 90 days post-MI). At 90 days post-MI, LVESV was increased significantly by 30%, whereas LVEF was reduced by 6.5%. VNS prevented these MI-induced changes in LVESV and LVEF (Table 1). Following echocardiographic recordings, IC ganglia, heart, and lungs were harvested. There was no significant difference in heart weight or lung weight (wet and dry) as percentage to body weight among all treated groups (Table 2).

IC neuronal properties. The membrane properties of IC neurons derived from MI (n = 7; 55 IC neurons), VNS-MI (n = 7; 55 IC neurons), and time-matched control guinea pigs (n = 8; 64 neurons) are summarized in Table 3. A significant depolarization (~5 mV) of the RMP in the MI group was identified compared with controls. VNS was effective in restoring these RMPs to control values. Neuronal input resistance increased significantly in the MI group. VNS mitigated overnight and washed for 5 min in TBS-T (5×) before incubation with goat anti-rabbit horseradish peroxidase-conjugated secondary antibody. Protein bands were detected using the Pierce SuperSignal West Pico Chemiluminescence Substrate (Thermo Fisher Scientific) in the G:Box Chemiluminescence and Fluorescence Imaging System. Serial exposure times in increments of 10 s were recorded for up to 2 min. For densitometry analysis, lower exposure times were selected to ensure linearity, whereas higher exposures are shown in figures for visual clarity. In some of the figures, blots were cut and rearranged strictly for presentational purposes; however, within rows, images were from the same blot and treated identically. Unless otherwise noted, all antibodies were purchased from Cell Signaling Technology (Beverly, MA) and used according to the manufacturer’s instructions. Band intensities were quantified using ImageJ software analysis.

Statistical analysis. Heart function using echocardiography was analyzed with a repeated-measures ANOVA to compare each animal with its baseline condition. The neuronal activity determined by intracranial current injections (see Figs. 1 and 2) was not normally distributed when analyzed using a Shapiro-Wilk test. A nonparametric Friedman test at the ordinal level and post hoc Wilcoxon signed-rank test with a Bonferroni correction were done to determine differences among study groups. The data related to tissue weights (see Table 2), neuronal transmembrane properties (see Fig. 3B), and myocyte function (see Figs. 4 and 5) were continuous and normally distributed by using a Shapiro-Wilk test. These data were analyzed using a simple or a mixed-model ANOVA, followed by a Newman-Keuls post hoc analysis. Results with P < 0.05 were considered statistically significant. Statistical analyses were conducted using SPSS software.

this MI-induced increase in input resistance. There were no significant differences in the amplitude or duration of the AHP half-decay times among IC neurons derived from all three groups.

Soma excitability was assessed by measuring the number of evoked action potentials in response to intracellular depolarizing current steps. Neuronal excitability increased in MI and VNS-MI groups compared with controls (Fig. 1). Previous studies demonstrated that chronic MI produces an increase in IC neuron sensitivity to NE, as seen in an increase in the number of evoked action potentials in response to depolarizing currents with NE application (38). In the current study, IC neuronal sensitivity to NE was increased in the MI group at lower (0.1 and 0.2 nA) and higher (0.4 and 0.5 nA) intensities compared with controls. Neural sensitivity also increased in the VNS-MI group at lower intensities (0.1 and 0.2 nA) compared with controls. Neural sensitivity also increased in the VNS-MI group at lower intensities (0.1 and 0.2 nA) compared with controls (Fig. 2).

**Synaptic efficacy.** Synaptic efficacy was evaluated among the three groups by measuring neuronal responses to stimulating axon bundles leading to the ganglion containing the neuron of interest (2 s suprathreshold train at 1, 2, 5, 10, and 20 Hz). Whereas the responses between MI and controls did not differ, the number of action potentials so produced was reduced significantly in the VNS-MI compared with MI and control animals (Fig. 3). The maximum neuronal output firing frequency was ~8 Hz in control and MI animals; it was reduced to ~4 Hz with chronic VNS.

**Myocyte function.** Three ventricular tissue samples were removed at time of termination, including from the infarct or CZ, the IZ, and a DZ. The ratio of the p-GS (inactive) to the active form of GS (GS) was determined by Western blot analysis in all three ventricular regions in control, MI, and VNS-MI heart samples. The VNS-MI heart tissue showed a significantly elevated p-GS/GS ratio compared with MI hearts in both the CZ and IZ (Fig. 4). In VNS-MI animals, the p-GS/GS ratio in the CZ was significantly higher compared with control animals (Fig. 4). Besides its role in glycolysis, GS is of interest as a downstream substrate of the key stress signaling kinase, GSK-3β, which is also regulated by phosphorylation. p-GSK-3β is inactive as a kinase but is considered the cardioprotective form of the protein (67). The ratio of p-GSK-3β/GSK-3 β decreased in the DZ of MI hearts compared with controls; this level was re-established in the CZ of the VNS-MI animals (Fig. 4).

To evaluate the potential of VNS to exert cardioprotection via modulation of the apoptotic pathway in cardiac myocytes, we evaluated the expression of several members of the mitochondrial apoptotic machinery (Bcl-2, Bcl-xL, and BAX) (56). No significant differences in the levels of Bcl-2 or Bcl-xL were identified (data not shown). However, the level of the proapoptotic protein BAX was elevated twofold in MI hearts. VNS mitigated the increase in BAX level, such that no difference was evident between control and VNS-MI group data (Fig. 5).

### DISCUSSION

MI remodels both the cardiac nervous system and the cardiac tissue that it modulates. These changes are dynamic, persisting for several weeks after the initial insult (36, 38). Associated with the loss of tissue (~8%) post-MI in the guinea pig, the interstitial tissue and the nerve terminals undergo substantial reorganization. After MI, the number of sympathetic nerve terminals in the infarct region decreases, whereas the number of sympathetic nerve fibers in the remote noninfarct region increases (38). This reorganization of the cardiac nervous system occurs predominantly via the vagus nerve, which regulates cardiac autonomic tone. VNS was shown to reduce cardiac remodeling in a guinea pig model of MI (56). In the current study, we explored the potential of VNS to exert cardioprotection via modulation of the apoptotic pathway in cardiac myocytes, and demonstrated that VNS mitigates the loss of tissue post-MI in the guinea pig.

**Fig. 1.** Evoked action potential (AP) frequencies with increasing intracellular stimulus intensities (0.1–0.6 nA, 500 ms) were determined by intracellular voltage recordings from intrinsic cardiac (IC) neurons in control preparations, in preparations at 90 days post-myocardial infarction (MI), and in preparations at 90 days post-MI that included 80 days of autonomic regulation therapy [vagus nerve stimulation (VNS)-MI], starting 10 days post-MI induction. A nonparametric Friedman test was used to test for differences among groups, with Wilcoxon signed-rank post hoc tests using a Bonferroni correction. Points represent the means ± SE from ~60 cells for each condition. *P < 0.05, control vs. MI and VNS-MI.

**Fig. 2.** Evoked action potential frequencies in response to increasing intracellular stimulus intensities were evaluated, concurrent with brief (1 s), local exposure to exogenous norepinephrine (NE) in IC soma derived from control animals and animals following MI, with and without chronic VNS. A nonparametric Friedman test was used to test for differences among groups, followed by Wilcoxon signed-rank post hoc tests using a Bonferroni correction. Points represent the means ± SE from ~60 cells for each condition. *P < 0.05, control vs. MI; #P < 0.05, control vs. VNS-MI.

Values expressed as means ± SE, with number of neurons shown. A Shapiro-Wilk test showed normality, and a significant effect (*P < 0.05) with ANOVA is shown for resting membrane potential and input resistance, MI vs. controls and VNS-MI. AHP, afterhyperpolarization.
The ICNS. Functional changes but also targeted MI-induced remodeling of neuronal properties. In this study, increased IC neuronal excitable collateral function, the level of cardiac damage induced by this MI was not sufficient for progression into congestive heart failure. At the cellular level, IC neurons post-MI displayed depolarization of their RMPs, increases in input resistance, and increased excitability. Since these IC neurons were not in the ischemic zone (i.e., their blood supply was uninterrupted), these IC neuronal changes presumably were a consequence of infarct-induced changes in afferent neuronal feedback to the ICNS (6, 36, 68). Presumably, they also reflect an MI reflex-induced decrease in parasympathetic efferent preganglionic neuronal drive (6, 11, 47).

The increase in the parasympathetic efferent neuronal drive to the ICNS by application of chronic VNS restored the IC neuronal RMPs and input resistances toward control values (Table 3). Furthermore, VNS also reduced synaptic efficacy by 50% for network interactions within the ICNS. The changes that VNS induced within the ICNS occurred in conjunction with the following: 1) preservation of LV function (as evidenced by echocardiographic data), 2) improvement in cardiomyocyte metabolic capacity, and 3) a reduced potential for ventricular myocyte apoptosis.

Regional LV MI produces an eccentric insult to the heart, which would change afferent neuronal signaling derived from the region where sensory neurites are located, namely, ischemic vs. normal zones. Such altered input is transduced to somata in IC, intrathoracic, and central components of the cardiac neuroaxis (22, 27, 68). Such alteration in afferent inputs has the potential to induce reactive changes in neuronal processing throughout the cardiac neuroaxis (2, 42, 68). With respect to IC neurons, such remodeling is most dynamic at 7 days post-MI, becoming stabilized by 14 days post-MI (1, 25, 36). In the current study, VNS was initiated during the peak of this remodeling process (cf. 7 days post-MI). As such, this strategy was effective in mitigating not only adverse cardiac functional changes but also targeted MI-induced remodeling of the ICNS.
that VNS, by reducing IC synaptic efficacy, will blunt
network hyperexcitability within the ICNS occurring sec-
ondary to ischemia-induced afferent feedback (46, 47). This
would be analogous to placing a governor on an internal
combustible engine. These neural influences are likely me-
diated via descending projections to local circuit neurons
contained within the ICNS (10, 30).

The second major neural influence derived from chronic
VNS therapy is its antiadrenergic influences. In large animal
studies, data demonstrate that peripheral sympathetic-parasymp-
thetic efferent interactions occur within IC ganglia (54, 58)
and at the efferent neural-myocyte interface [both presynaptic
(49) and postsynaptic (48)]. Both preclinical (70, 71) and
clinical (20, 57) studies indicate that the benefits of VNS can
be made manifest at stimulation levels that exert minimal
effects on resting heart rate. Since the cervical vagus is a mixed
nerve, 80% of which is afferent fibers (12, 72), it is the
interaction among multiple levels of the cardiac neural hierar-
chy that ultimately determines functional effects on target
organs (4, 7, 12, 53).

Cardiomyocyte function. Examination of the metabolic en-
zeyme markers in ventricular myocytes demonstrated a clear
trend of increasing the p-GS/GS ratio in normally perfused
tissue located more distal to the arterial ligation in VNS-MI
hearts. Increases in the p-GS/GS ratio represent an increase in
glycogen use rather than storage via inactivation of glycogen
synthetic enzymes. These results indicate that VNS supports
glycogen mobilization and glucose use in recovering and/or
compensating cardiac tissues. Whereas additional work is
needed to ascertain the precise nature of the effects of VNS on
such glucose metabolism and whether the increased p-GS/GS
ratio indeed represents an upregulation of glycogenolysis,
these data suggest that VNS exerts a profound regulatory
influence upon glycogen metabolism in the post-MI heart.

Glucose provides more ATP per mole of O$_2$ than free fatty
acids (FFA). Shifting metabolism from FFA oxidation to
glucose oxidation has been suggested as a therapeutic approach
in heart failure (65, 66). Whereas cardiac tissue has a relatively
small pool of glycogen, its turnover rates are high—reported
to account for \( \leq 40\% \) of glucose-derived ATP production (40). As
mobilization of glycogen stores represents a classic response to
ischemia, any increase in phosphorylation of GS post-MI with
VNS suggests less glycogen synthesis. This, in turn, implies
more glucose use. Since the border and CZs have less O$_2$
availability, glucose therein would be available for anaerobic
metabolism.
Multiple stress pathways converge upon GSK-3β, such that it has emerged recently as a pivotal cardioprotective molecule. p-GSK-3β inhibits its kinase activity and increases its cardioprotective potential through poorly understood effects at the mitochondrial level (67). The current study did not show any decrease in p-GSK-3 in tissue samples with increased p-GS/GS ratios. This finding indicates that increased GSK-3β activity is not responsible for the higher p-GS/GS ratio that we observe in these samples. Since a multitude of other kinases and phosphatases exerts regulatory influence upon GS, any disconnect between the apparent activity of p-GSK-3β and p-GS status is not entirely unexpected. Regardless of the influence of GSK-3β on GS under these particular circumstances, the findings of an increased p-GSK-3β/GSK-3β ratio, as well as the normalization of the mitochondrial proapototic protein BAX in VNS-treated hearts, potentially represent important findings pertinent to cardioprotection. These cellular data are especially relevant when considered in light of evidence of improved function of VNS-MI hearts in both small (Table 1) and large animal models of ischemic heart disease (51, 62, 71).

Study limitations. Whereas we were able to demonstrate functional manifestations of VNS-mediated cardioprotection, no histopathologic results from the ventricles were performed in parallel to confirm such molecular findings—the former being a more sensitive index of change. Correspondingly, in the past, we have identified no histological changes in the ICNS unless there is direct obstruction of the arterial supply of neurons so targeted (6, 42). As this was not the case in this study, we did not attempt to detect histologically changes to neuronal somata that had normal blood supplies. As for VNS, we evaluated only one frequency (20 Hz) at a stimulus intensity where afferent- and efferent-evoked responses balanced each other, such that little or no heart rate changes were evoked (45). As such, VNS was able to engage the cardiac nervous system while minimizing the potential for rebound effects during the off phase that accompanies the intermittent VNS protocol. Future studies should evaluate other VNS stimulus paradigms (duty cycle, frequency, intensity, and pulse width). Finally, we did not characterize the phenotype of the IC neurons being recorded (41) nor could we distinguish between postganglionic soma and interneurons contained within the IC nervous system (7) with the techniques used. At least in the guinea pig model, the IC neurons recorded with sharp electrodes have been shown to be primarily cholinergic (52). Future studies should consider the possible contribution of cardiac disease-induced changes in IC neural phenotype (29) and network interactions contributing to autonomic dysautonomia associated with ischemic and nonischemic heart disease (26, 29, 61).

Significance and perspectives. VNS is an emerging neuromodulation therapy that is currently being evaluated for treating cardiac arrhythmias (13, 74) and heart failure (21, 57, 59). In animal models, the deleterious consequences of MI on cardiac structure and function have been shown to be attenuated by chronic VNS, such that survival improves (51, 71). VNS protects cardiomyocytes against apoptosis (43, 44), mitigates mitochondrial dysfunction (62), and reduces the inflammatory responses (15, 69). At the level of the ICNS, VNS does not alter MI-induced increases in neuronal excitability; VNS did reduce ICNS synaptic efficacy; and VNS can exert antiautonomic effects within peripheral autonomic ganglia (54, 58) and at their end-terminus (49). Together, these effects of VNS would moderate overall network processing within the ICNS in transducing myocardial ischemia to shift the autonomic balance at the neural-myocyte interface away from pathological levels of adrenergic hyperactivity (7, 45). VNS, both directly and indirectly (via the nervous hierarchy), improved cardiac myocyte metabolic function, while reducing cardiac myocyte apoptotic state.

VNS is currently in multiple clinical trials for reduced ejection-fraction heart failure (14, 19). These include the Increase of Vagal Tone in CHF (INOVATE-HF), Neural Cardiac Therapy for Heart Failure (NECTAR-HF), and Autonomic Neural Regulation Therapy to Enhance Myocardial Function in Heart Failure (ANTHEM-HF). Initial reports of these trials have been positive for INOVATE-HF and ANTHEM-HF, with neutral effects for NECTAR-HF (20, 21, 57). One of the key differences among these trials is the choice of stimulation parameters (current, frequency, pulse width, and duty cycle) and especially, the different levels of stimulus intensity. The understanding mechanistically of what is being stimulated within the autonomic nervous system by any bioelectric therapy and how the neural network-heart interface reacts to such stimuli is essential for optimizing stimulation parameters and for the future development of effective autonomic regulation therapies (14). As demonstrated here, targeted VNS exerts multiple effects on the cardiac nervous system and the cardiac tissues it regulates and ultimately, preserves contractile function and as such, cardiac output.

GRANTS
Support for this work was provided by the National Heart, Lung, and Blood Institute (Grants HL71830 to J. L. Ardell and HL09889 to J. C. Hardwick and E. M. Southerland) and by Cyberonics (to J. L. Ardell).
