Trangmar SJ, Chiesa ST, Llodio I, Garcia B, Kalsi KK, Secher NH, González-Alonso J. Dehydration accelerates reductions in cerebral blood flow during prolonged exercise in the heat without compromising brain metabolism. Am J Physiol Heart Circ Physiol 309: H1598–H1607, 2015. First published September 14, 2015; doi:10.1152/ajpheart.00525.2015.—Dehydration hastens the decline in cerebral blood flow (CBF) during incremental exercise, whereas the cerebral metabolic rate for O2 (CMRO2) is preserved. It remains unknown whether CMRO2 is also maintained during prolonged exercise in the heat and whether an eventual decline in CBF is coupled to fatigue. Two studies were undertaken. In study 1, 10 male cyclists cycled in the heat for ~2 h with (control) and without fluid replacement (dehydration) while internal and external carotid artery blood flow and core and blood temperature were obtained. Arterial and internal jugular venous blood samples were assessed with dehydration to evaluate CMRO2. In study 2, in 8 male subjects, middle cerebral artery blood velocity was measured during prolonged exercise to dehydration in both dehydrated and euhydrated states. After a rise at the onset of exercise, internal carotid artery flow declined to baseline with progressive dehydration (P < 0.05). However, cerebral metabolism remained stable through enhanced O2 and glucose extraction (P < 0.05). External carotid artery flow increased for 1 h but declined before exhaustion. Fluid ingestion maintained cerebral and extracranial perfusion throughout nonfatiguing exercise. During exhaustive exercise, however, euhydration delayed but did not prevent the decline in cerebral perfusion. In conclusion, during prolonged exercise in the heat, dehydration accelerates the decline in CBF without affecting CMRO2 and also restricts extracranial perfusion. Thus, fatigue is related to a reduction in CBF and extracranial perfusion rather than CMRO2.

cerebral blood flow; dehydration; extracranial blood flow; prolonged exercise

NEW & NOTEWORTHY

Reductions in cerebral blood flow and extracranial perfusion, induced by dehydration during prolonged exercise in the heat, may be coupled to fatigue. However, cerebral metabolism remains stable through enhanced O2 and glucose extraction. Thus, fatigue developed during prolonged exercise with dehydration is related to reductions in cerebral blood flow rather than to the cerebral metabolic rate for O2.

Dehydration and hyperthermia accrued during prolonged exercise in the heat pose a challenge to cardiovascular control, evidenced by reductions in stroke volume, cardiac output, skeletal muscle and skin blood flow, and, to a lesser extent, mean arterial pressure (MAP) (12, 16, 29). The cardiovascular strain imposed by combined dehydration and hyperthermia might also encompass cerebral blood flow (CBF) as an orthostatic challenge (35), pharmacological interventions that depress cardiac output (19), passive heat stress (2, 31), and combined heat stress and exercise (34) compromise cerebral perfusion. However, the role of hydration on the effect of prolonged exercise-induced dehydration on CBF and cerebral metabolism [cerebral metabolic rate of O2 (CMRO2)] is unknown.

Reductions in O2 and substrate supply can compromise organ and tissue metabolism (13) and the circulatory strain induced by dehydration during prolonged exercise in a hot environment may compromise cerebral substrate delivery to an extent that impairs CMRO2 and central nervous system function, ultimately curtailing performance. CMRO2 is maintained during incremental exercise (44, 15), but it remains unknown whether CBF and CMRO2 are preserved during prolonged exercise in the heat or whether eventual deviations relate to fatigue. Thermoregulatory processes increase and modify the distribution of skin and deep tissue blood flow (6, 7) to regulate body temperature during exercise, particularly during heat stress (14). Across the head circulation, increasing skin and body temperatures lead to progressive elevations in external carotid artery (ECA) blood flow, as evidenced during incremental exercise in normothermia (40) and with passive heat stress (2, 36). The ECA serves the cutaneous circulation of the neck and face, which is important for heat liberation. In contrast, CBF progressively declines at high exercise intensities and with high body temperatures (36, 41). Altered perfusion pressure, blood gas tensions [particularly arterial Pco2 (PaCO2)] (48) and sympathetic activity (28) have been implicated in the control of CBF, whereas body temperature is known to influence ECA blood flow (36, 40, 41). However, no study has, as yet, characterized the regional distribution of blood flow across the head during prolonged exercise with and without progressive reductions in total body water.

The aim of the present study, therefore, was to assess the effect of dehydration on cerebral and extracranial hemodynamics and CMRO2 during prolonged exhaustive exercise in the heat. A second aim was to gain insights into the potential mechanisms underlying CBF responses to dehydration and prolonged exercise during nonexhaustive and exhaustive exercise. We hypothesized that dehydration accrued during prolonged exercise in the heat would reduce CBF but that CMRO2 would be maintained. A second hypothesis was that ECA blood flow would increase in relation to increasing core temperature. Finally, we hypothesized that the cerebral circulatory strain occurring during strenuous exercise in the heat is an...
epiphenomenon of fatigue rather than the direct consequence of dehydration.

METHODS

Fully informed written consent was obtained from the participants before the studies. All procedures were approved by the Brunel University London Research Ethics Committee (RE07-11 and RE20-09) and conformed with guidelines of the World Medical Association (Declaration of Helsinki).

Ten healthy endurance-trained male subjects [means ± SD; age: 29 ± 5 yr, height: 183 ± 5 cm, body mass: 78 ± 9 kg, and maximal O₂ consumption (VO₂ max): 59 ± 6 ml·kg⁻¹·min⁻¹] participated in study 1. In study 2, the age, height, body mass, and VO₂ max of the eight endurance-trained male subjects were 33 ± 4 yr, 173 ± 4 cm, 75 ± 11 kg, and 56 ± 7 ml·kg⁻¹·min⁻¹, respectively. All participants arrived at the laboratory with normal hydration status and were required to have abstained from alcohol intake for 24 h and caffeine consumption for 12 h.

Experimental protocols. The experimental design of study 1 has been previously described (44). Participants visited the laboratory for 3 preliminary trials followed by 2 experimental trials, each separated by at least 1 wk. During the preliminary trials, participants were familiarized with the methodology before completing incremental exercise on a semirecumbent cycle ergometer (Lode Angio, Groningen, The Netherlands), with a backrest inclination of 45°, to establish the maximal work rate, maximal heart rate (HR), and VO₂ max. Participants were then familiarized to the heat and experimental protocol by cycling in an environmental chamber set at 35°C (relative humidity: 50%) in the semirecumbent position for 2 h at 55% of the maximal work rate with HR and intestinal temperature recorded. No fluid consumption was permitted during exercise. To determine hydration status, body mass was recorded before and after the studies. All procedures were approved by the Brunel University London Research Ethics Committee (RE07-11 and RE20-09), and the experimental design of study 2 was observed between catheterization and the commencement of resting measurements.

Blood variables. Arterial and jugular venous blood samples were drawn into preheparinized syringes and analyzed immediately for blood gas variables (ABL 800 FLEX, Radiometer, Copenhagen, Denmark), corrected for blood temperature in the internal jugular vein. The analyzer was calibrated at regular intervals in accordance with manufacturer guidelines. Additional arterial and jugular venous blood were collected in 2-ml syringes, transferred to EDTA tubes, centrifuged, and separated. Plasma epinephrine and norepinephrine (NE) were subsequently determined using an enzyme-linked immunosassay kit (DEE6500 2-CAT, Demeditec Diagnostics).

HR, blood pressure, and temperature. HR was obtained by telemetry (Polar Electro, Kempele, Finland). Arterial and internal jugular venous pressure waveforms were recorded using transducers (Pressure Monitoring Kit, TruWave, Edwards Lifesciences) zeroed at the level of the right atrium in the midaxillary line (arterial) and at the level of the tip of the catheter (jugular venous). During the control trial, reconstituted brachial artery pressure waveforms were obtained noninvasively (Finometer Pro, Finapress Medical Systems). Arterial pressure waveforms were sampled at 1,000 Hz, amplified (BP Amp, ADInstruments, Oxfordshire, UK), and connected to a data-acquisition unit (Powerlab 16/30, ADInstruments) for offline analysis. Intestinal temperature was measured using an ingestible telemetry pill (HP, Palmetto, FL), and mean skin temperature was obtained using a wired thermocouple system (TC-2000, Sable Systems) from standard weightings of chest, abdomen, thigh, and calf temperatures (38).

Calculations. Cerebral vascular conductance indexes were calculated by dividing blood flow in the ICA, ECA, CCA, and MCA (Vmean) by MAP. Arterial O₂ content was used to quantify O₂ delivery through the ICA and MCA, respectively. CMRO₂ and cerebral glucose and lactate uptake were calculated as ICA flow × 2, multiplied by the corresponding arterial to venous difference. The molar ratio of O₂ to
glucose \([\text{O}_2\text{-to-glucose index (OGI)}]\) and \(\text{O}_2\text{-to-carbohydrate index (OCI; } \text{O}_2/\text{glucose } + \frac{1}{2}\text{lactate index) were also calculated.}

**Statistical analysis.** All analyses were made using IBM SPSS Statistics (version 20, IBM, Armonk, NY). Variables were assessed using two-way repeated-measures ANOVA in which condition (dehydration and control) and exercise phase (rest, 30, 60, 90, and 120 min) were the main factors, with the Dunn-Sidak correction used for multiple comparisons. Multiple regression for within-subject repeated measures was used for analysis of the relationship between blood flow and blood gas variables and temperature (3). Data are presented as means ± SE, and the α-level for significance was set at \(P < 0.05\).

**RESULTS**

*Hydration and temperature.* Exercise without supplementation of fluid resulted in a 3% body mass reduction (78.2 ± 2.7 to 75.8 ± 2.7 kg) and a 10-min reduction in exercise duration (110 ± 2 vs. 120 min in the control trial, both \(P < 0.001\)). In the control trial, body mass was maintained at the preexercise level (79 ± 3 kg) through the consumption of fluid (~1.2 l/h). The decline in body mass with dehydration was accompanied by increases in arterial and venous hemoglobin content (\(P < 0.05\)), indicative of plasma volume reductions. Intestinal temperature increased progressively in both trials but was higher at the end of exercise in the dehydration trial compared with the control trial (38.7 ± 0.1 vs. 38.2 ± 0.2°C, \(P < 0.05\); Table 1). Internal jugular venous blood temperature mirrored the rise in intestinal temperature in the dehydration trial (see Fig. 4B).

Mean skin temperature was maintained throughout exercise in both dehydration and control trials (~32.8 and ~32.6°C; Table 1). HR was similar at rest but during the second h of exercise was maintained at ~14 beats/min higher in the dehydration trial compared with the control trial (\(P < 0.05\)).

*Brain and extracranial hemodynamics and metabolism.* In the dehydration trial, ICA blood flow and MCA \(V_{\text{mean}}\) increased by ~12% at 30 min (\(P < 0.05\)) before declining progressively to baseline values at the end of exercise (\(P < 0.05\); Fig. 1, A and D). The decline in ICA blood flow was associated with a reduction in blood flow velocity (\(P < 0.05\)) but not in vessel diameter. On the other hand, in the control trial, ICA blood flow and MCA \(V_{\text{mean}}\) increased and remained stable throughout exercise. During the dehydration trial, ECA (and CCA) blood flow almost doubled from rest to 90 min (0.42 ± 0.03 to 0.74 ± 0.04 l/min) but then declined at the end of exercise (\(P < 0.05\); Fig. 1, B and C). In contrast, during the control trial, ECA flow increased similarly up to 90 min of exercise and then plateaued.

The decline in ICA blood flow at the end of dehydration exercise was accompanied by an increased arterial to venous \(\text{O}_2\) difference (\(P < 0.05\)) but no changes in the arterial to venous \(\text{CO}_2\) difference or brain \(\text{CO}_2\) output index. Thus, \(\text{CMRO}_2\) was stable throughout exercise. Both arterial and jugular venous plasma glucose gradually declined throughout prolonged exercise (5.4 ± 0.2 to 5.1 ± 0.2 and 5.4 ± 0.2 to 4.4 ± 0.2 mmol/l, respectively, \(P < 0.05\)). However, the brain arterial to venous glucose difference was stable during the early stages of exercise before increasing before the end of exercise (peak value of 0.7 mmol/l, \(P < 0.05\); Fig. 2A), whereas brain glucose uptake increased initially (0.33 to 0.43 mmol/min, \(P < 0.05\); Fig. 2B) and then remained stable.

At rest, the brain released a small amount of lactate (0.2 ± 0.05 mmol/l), and during prolonged exercise with dehydration, arterial and jugular venous lactate gradually declined (3.4 ± 2.4 to 3.0 ± 0.3 and 3.6 ± 0.5 to 2.4 ± 0.3 mmol/l, \(P < 0.05\)). The brain arterial to venous lactate difference was maintained throughout exercise, as was lactate exchange (Fig. 2, D and E). The molar ratio of \(\text{O}_2\) to glucose declined at the onset of exercise (6.1 ± 0.5 vs. 4.5 ± 0.3, \(P < 0.05\); Fig. 2C) and thereafter remained stable, with a similar response when lactate metabolism was accounted for (Fig. 2F).

*Brain extracranial vascular conductance.* In the dehydration trial, MAP increased ~18% from rest to 30 min (105 ± 3 to 124 ± 4 mmHg, \(P < 0.05\)) before declining progressively until exercise termination (\(P < 0.05\)). In the control trial, MAP increased by 11% from rest to 30 min and then remained stable. During prolonged exercise, ICA and MCA \(V_{\text{mean}}\) vascular conductance were lower in the dehydration trial compared with the control trial (\(P < 0.05\)). At the end of exercise in the dehydration trial, both ICA and MCA \(V_{\text{mean}}\) vascular conductance indexes were reduced (\(P < 0.05\); Fig. 3), whereas in the control trial, they remained stable. CCA and ECA vascular conductance were similar between trials during early exercise but were reduced at the end of exercise in the dehydration trial compared with the control trial (\(P < 0.05\)).

*Blood flow and \(\text{PaCO}_2\), plasma catecholamines, and temperature.* In the dehydration trial, \(\text{PaCO}_2\) declined to below baseline at the end of exercise (~6% reduction from the peak value, \(P < 0.05\); Fig. 4A), whereas venous \(\text{PCO}_2\) remained unchanged throughout exercise. During exercise, the decline in both ICA blood flow (\(R^2 = 0.44\); Fig. 4C) and MCA \(V_{\text{mean}}\) (\(R^2 = 0.5\); data not shown) were correlated with reduced \(\text{PaCO}_2\) (both \(P < 0.01\)) and, to a weaker extent, also with arterial NE.

Values are means ± SE for 10 participants. Data presented are from the dehydration trial only. *\(P < 0.05\) vs. rest; †\(P < 0.05\) vs. 30 min; ‡\(P < 0.05\) vs. control.
concentration ($R^2 = 0.15, P < 0.05$) but not to with jugular venous NE concentration ($R^2 = 0.02, P = 0.58$).

In the dehydration trial, arterial epinephrine concentration increased from rest to 30 min ($0.7 \pm 0.2$ to $1.1 \pm 0.2$ nmol/l, $P < 0.05$) but remained stable throughout exercise (range: $1.1$–$2.7$ nmol/l), whereas jugular venous epinephrine concentration did not increase until after 90 min of exercise ($110 \pm 2$ min $= 2.3 \pm 0.7$ nmol/l, $P < 0.05$ vs. rest). Arterial NE concentration increased to a peak of $33 \pm 8.2$ nmol/l ($P < 0.05$ vs. rest), whereas jugular venous NE concentration increased to 90 min ($3.6 \pm 1.2$ to $31.0 \pm 5.2$ nmol/l, $P < 0.01$) before declining before exhaustion (14.1 ± 1.2 nmol/l), indicating the cerebral uptake of catecholamines at exhaustion.

The alterations in ECA blood flow and vascular conductance were associated with increases in internal jugular venous blood temperature ($R^2 = 0.48, P < 0.01$; Fig. 4, B and D) and jugular
venous NE concentration ($R^2 = 0.48$, $P < 0.01$). However, a consistent relationship with blood temperature was not observed beyond 90 min, where the 7% decline in ECA blood flow (and conductance) was matched with an increased blood temperature (Fig. 4B).

**Hydration, core temperature, and the cerebral circulation during exhaustive exercise.** Hydration status was the same before exercise, as indicated by the same body mass in both trials (75.2 ± 4.2 and 75.3 ± 4.2 kg). When participants did not ingest fluids during exercise, they became progressively dehydrated to a 3.2 ± 0.3% reduction in body mass, whereas they maintained body mass in the euhydration trial (+0.3 ± 0.2% body mass). In addition, they became exhausted sooner in the dehydrated state than when euhydrated (123 ± 7 vs. 145 ± 9 min, $P < 0.05$), with higher core temperature and HR at exhaustion (38.7 ± 0.2 vs. 38.3 ± 0.1°C and 156 ± 4 vs. 148 ± 5 beats/min, both $P < 0.05$). Core and skin temperatures and HR, however, were similar between trials during the first 40–50 min of exercise. MCA $V_{\text{mean}}$ increased during the first 30 min of the exercise and thereafter declined in both trials ($P < 0.05$ vs. the 30-min value).

**DISCUSSION**

The main finding of the present study is that dehydration impaired prolonged exercise capacity in the heat in association with an accelerated reduction in CBF. However, despite the reduced CBF, cerebral metabolism was preserved by elevated O$_2$ and glucose extraction from blood. A second novel finding was that in both experimental trials, the rise in ECA blood flow was attenuated before volitional exhaustion. The reduction in CBF was related to reduced PaCO$_2$, whereas increased ECA vascular conductance was associated with increasing internal temperature. Although maintenance of euhydration by fluid...
ingestion preserved cerebral and extracranial blood flow throughout nonfatiguing exercise, it only delayed the decline in CBF during exhaustive exercise. These findings suggest the CBF decline with dehydration is coupled to factors associated with the fatigue processes rather than dehydration per se.

Cerebral and extracranial hemodynamics. A first aim of the study was to characterize hemodynamic responses of the cerebral and extracranial circulations to dehydration during prolonged exercise in the heat. We found that after the well-established increase upon the onset of exercise, CBF and MCA V_{mean} declined gradually to resting values at volitional exhaustion concomitant with the development of dehydration. Conversely, when hydration was maintained during similar duration exercise, CBF did not decline. Similarly, CBF remains stable during prolonged exercise in a thermoneutral environment when the degree of dehydration is negligible (33, 34). However, when exercise in a warm environment causes hyperthermia and cardiovascular strain, CBF is suppressed (37) before declining to resting values (34). These studies, however, did not establish whether hyperthermia, dehydration, or other factors underpinning volitional exhaustion are responsible for the fall in CBF. An important observation from a parallel study (study 2) was that cerebral perfusion gauged by MCA V_{mean} declined when control (euhydration) exercise was continued to exhaustion and core temperature remained at normothermic levels (Fig. 5). Taken together, the findings from both studies...

Fig. 3. Blood pressure and cerebral and extracerebral vascular conductance during prolonged exercise. Values are means ± SE for 10 participants. A: blood pressure. B: ICA vascular conductance. C: MCA vascular conductance. D: CCA vascular conductance. E: ECA vascular conductance. *P < 0.05 vs. rest; †P < 0.05 vs. the 30-min value.
indicate that CBF declines during exhaustive exercise regardless of the hydration status and the level of core temperature, yet the maintenance of euhydration and stable core temperature slows the rate of the CBF decline late in fatiguing exercise. The CBF decline with dehydration is therefore closely coupled to factors associated with the fatigue processes rather than reduced body fluids or core hyperthermia per se.

Another pertinent finding was that blood flow to extracranial tissues displayed a distinct temporal dynamic response to that of the cerebral circulation but was blunted late in exercise in the dehydrated condition. These findings agree with reports of two- to threefold increases in ECA blood flow in response to passive heat stress (2, 36) and incremental exercise (40). The ECA supplies blood to the skin circulation of the face and neck. In this light, the enhanced ECA perfusion may be part of circulatory adjustments required to meet the thermoregulatory demands for heat transfer to the environment surrounding the head (36). Collectively, these data suggest that dehydration accentuates the rise in internal temperature, reduces extracranial blood flow at point of exhaustion, accelerates the decline in cerebral perfusion, and leads to early exhaustion during prolonged exercise in the heat.

Regional head blood flow regulation. Both local and systemic factors have been implicated in the regulation of CBF through modulation of vascular conductance (or resistance) and cerebral perfusion pressure. The decline CBF in the dehydration trial was accompanied by a falling cerebrovascular conductance, indicative of augmented vasoconstriction. Changes in blood gas variables (48) and sympathetic activity (28) may play a role in the control of CBF during conditions including exercise. In particular, CO₂ is a potent vasoactive substance within the cerebral vasculature, with reductions in PaCO₂ inducing cerebral vasoconstriction and increases leading to vasodilation (2, 25, 48). The decline in PaCO₂ is attributed to hyperventilation with increasing exercise intensity and a rising core body temperature (46, 47). Thus, the decline in vascular conductance with dehydration was associated with reductions in PaCO₂ (R² = 0.44, P < 0.01; Fig. 4C) and cerebral perfusion pressure but unrelated to the stable arterial and internal jugular venous O₂ variables (data not shown). PaCO₂, however, accounted for only half of the variance in vascular conductance, and there was only a modest relationship between CBF and cerebral perfusion pressure (R² = 0.18, P < 0.05). Another potential contributing factor is enhanced sympathetic activity. The cerebral vasculature is richly innervated with sympathetic nerves, and observations of NE spillover into the internal jugular venous outflow, as seen here with dehydration, may reflect sympathetic-mediated vasoconstriction of the cerebral vessels (28, 50). However, despite increases in arterial and jugular venous NE concentration, the relationships between cerebrovascular tone and plasma NE were weak (43, 46a, 49).

The distinct dynamics of the extracranial circulation might involve different regulatory mechanisms. There was a close coupling between the increase in ECA blood flow/conductance and the rise in internal jugular blood temperature (R² = 0.64, P < 0.01; Fig. 4D). We did not investigate the control of skin
blood flow, but cutaneous blood flow is enhanced by elevated local and core temperatures (5, 21, 39). The role of sympathetic activity in the response to local and internal temperature changes is substantiated by an elevation in skin sympathetic nerve activity (7, 32), promoting cutaneous blood distribution and sudomotor function (5, 24). With a similar ECA profile in both trials, it is more likely that exercise per se attenuates cutaneous perfusion as rising internal temperature (above 38°C) is not matched by further increases in skin perfusion, as measured in the forearm (4, 17). Dehydration also limits maximal skin perfusion during exercise (30) and enhances systemic vascular resistance (16), leading to attenuated cutaneous blood flow (23). Taken together, these findings support that blood flow to the extracranial vascular bed is influenced by local and internal temperatures and enhanced sympathetic activity.

**Impact of dehydration on cerebral metabolism.** A reduction in O2 supply can compromise organ metabolism, as shown in contracting skeletal muscle with significant hyperthermia during maximal exercise (13). Here, we asked whether prolonged fatiguing exercise and dehydration compromise cerebral metabolism. Similar to findings during maximal exercise (44), the decline in CBF was met by an equal increase in O2 extraction such that CMRO2 was maintained during prolonged exercise in the dehydrated state, in agreement with other independent metabolic measures obtained in this study. In addition, glucose uptake, cerebral lactate exchange, OGI, and OCI remained unchanged, and the cerebral respiratory quotient (∼1.03) was stable (8). There is contrasting evidence that CMRO2 might be elevated during strenuous exercise combined with severe hyperthermia compared with control exercise (33), thereby suggesting that the metabolic demand of the brain increases during exhausting exercise. This conclusion, however, is based on two data points. To provide a more comprehensive account of the cerebral metabolic responses to exercise and establish whether CMRO2 is altered during fatiguing exercise, we plotted the anterior CBF and arterial to venous O2 difference data from the current prolonged exercise protocol together with the reported

---

AJP-Heart Circ Physiol • doi:10.1152/ajpheart.00525.2015 • www.ajpheart.org
baseline and incremental exercise data obtained in the same individuals (Fig. 6) (44). This analysis showed that CMRO₂ remained stable across a variety of exercise intensities, exercise durations, hydration conditions, and rest-to-exercise transitions, as variations in CBF were met by proportional changes in O₂ extraction. The unchanged global cerebral metabolism may reflect a balance of regional alterations in metabolic (and thus flow) demand. In this construct, exercise of increasing intensity both augments and downregulates regional blood flow across the brain (9). It remains to be clarified whether regional cerebral hyperperfusion, particularly that assessed in the frontal cortex, reflects an important process leading to fatigue or a selective downregulation in neuronal activity in regions of the brain that are less important during physical exertion (10). Restoration of CBF and cerebral oxygenation during strenuous exercise in the heat does not affect the development of fatigue (22). Therefore, although regional differences might exist, our data suggest that metabolic activity of the brain as a whole is neither enhanced nor compromised during exhaustive exercise in trained healthy individuals.

Experimental considerations. Ultrasound imaging of extracranial vessels and MCA V̅mean are appropriate for assessing CBF during dynamic exercise in an upright position (18, 40, 44). Notwithstanding, some flow is directed to branch vessels (e.g., the choroidal artery), but this is unlikely to impact on the measured CBF during exercise (27). Furthermore, changes in MCA V̅mean may underestimate cerebral perfusion as vessel diameter changes are unknown. However, during exercise, changes in MCA V̅mean are similar to absolute blood flow measured in the ICA (18). Blood samples were obtained from the left internal jugular vein and asymmetry may be present in the venous drainage of the brain (42). However, blood gas variables obtained from the left and right internal jugular vein are similar both at rest and during exercise (11, 20). We were unable to obtain internal jugular venous blood samples in the control trial, but it has been demonstrated that leg and systemic arterial to venous O₂ differences are stable when euhydration is maintained during prolonged exercise in the heat (12). We therefore expect that arterial to venous O₂ differences across the brain would also be unchanged when CBF is not compromised. Finally, the present studies used only male participants. Previous studies using both male and female participants have not demonstrated any sex differences in CBF responses to exercise (40).

Conclusions. Dehydration leads to augmented cerebrovascular strain, as indicated by blunted cerebral and extracranial perfusion during prolonged exercise in the heat. However, despite the circulatory strain associated with fatigue, secondary to dehydration and hyperthermia, cerebral metabolism is not impaired due to compensatory increases in O₂ and substrate extraction across the brain. The findings imply that reduced cerebral metabolism is unlikely to explain the reduced exercise capacity with dehydration during prolonged exercise in the heat. In contrast, both a reduction in CBF and extracranial perfusion may influence fatigue.

ACKNOWLEDGEMENTS

The authors thank all participants for their time, effort, and commitment, without which this work would not have been possible. The authors also thank Christopher Stock and Andrew Simpson for the technical assistance throughout the invasive study.
